Status of Big Skate (*Beringraja binoculata*) Off the U.S. Pacific Coast in 2019

Contents

Executive Summary

Stock

This assessment reports the status of the Big Skate (*Beringraja binoculata*) resource in U.S. waters off the West Coast using data through 2018. A map showing the area of the U.S. West Coast Exclusive Economic Zone covered by this stock assessment is provided in Figure a.

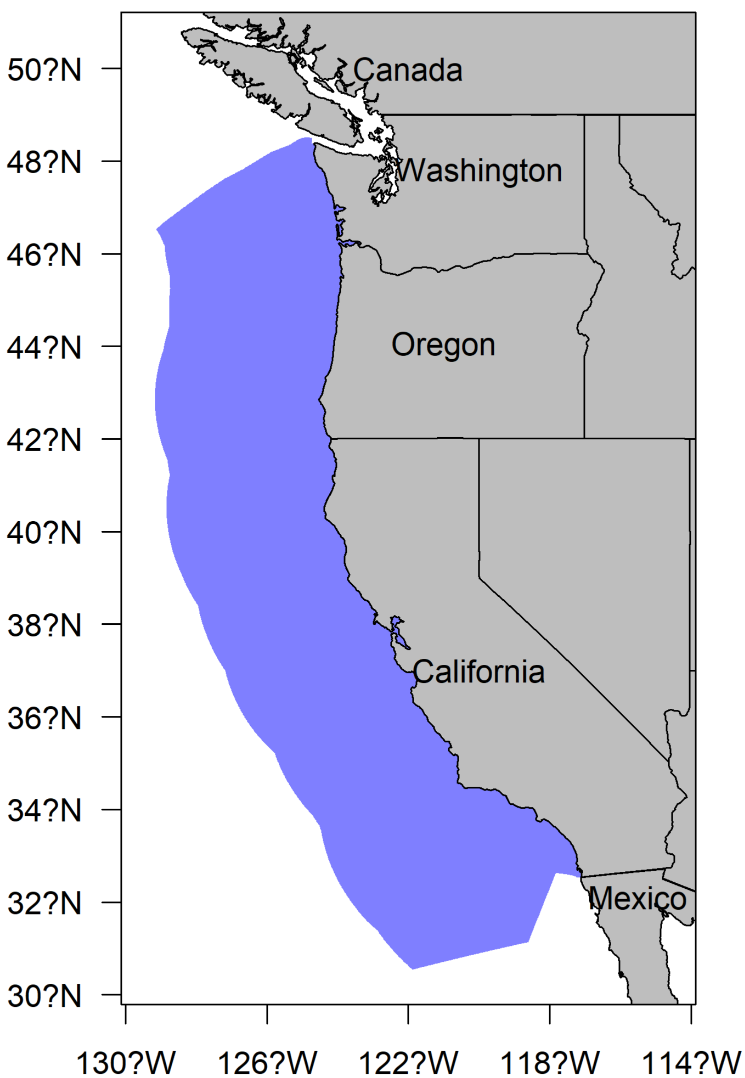

Figure a: U.S. West Coast Exclusive Economic zone covering the area in which this stock assessment is focused.

Catches

Landings and estimated discards of Big Skate were reconstructed for this assessment from historical records of other species and from species composition data collected in the recent fishery. These reflect the fishery from 1916-1994. The current fishery started in 1995. For records from 1995-2017, Big Skate landings were estimated from species-composition samples and the landings of "Unspecified Skates". Beginning in 2017, Big Skate have been recorded in species-specific landings.

In the current fishery (since 1995), annual total landings of Big Skate have ranged between 135-528 mt, with landings in 2018 totaling 173 mt.

Table a: Recent Big Skate landings (mt)

Year	Landings
2008	366.00
2009	205.70
2010	196.20
2011	268.40
2012	269.60
2013	135.00
2014	372.40
2015	331.50
2016	411.50
2017	277.60
2018	172.60

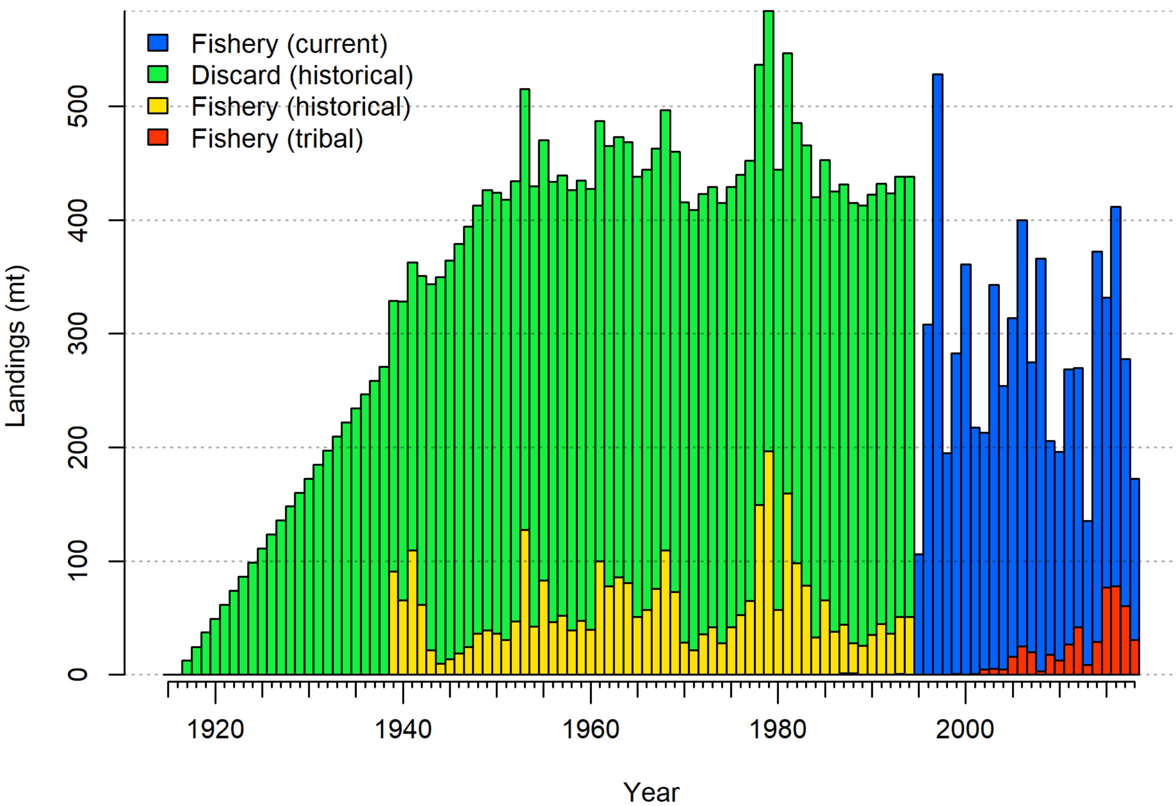

Figure b: Catch history of Big Skate in the model.

Data and Assessment

This the first full assessment for Big Skate. It is currently managed using an OFL which was based on a proxy for F_{MSY} and a 3-year recent average of survey biomass. This assessment uses the newest version of Stock Synthesis (3.30.13). The model begins in 1916, and assumes the stock was at an unfished equilibrium that year.

The assessment relies on two bottom trawl survey indices of abundance, the Triennial Survey from an index covering the period 1980–2004 was used here and the West Coast Groundifish Bottom Trawl (WCGBT) Survey, which began in 2003 and for which data is available through 2018. The triennial survey shows an increasing trend over the 25 year period it covers, which the model is not able to fit as this includes the peak period of the fishery when the stock would have been expected to be declining. The WCGBT Survey also shows an increasing trend, with the 5 most recent observations (2014–2018) all falling in the top 6 ever observed (2004 was the 5th highest observation). The most estimates an increasing trend during this period but the slope is more gradual than the trend in the survey. The misfit to these survey indices could be due to some combination of incorrect estimation of the catch history, variability in recruitment which is not modeled here, or biological or ecological changes for which data are not available.

Length composition data from the fishery is available starting in 1995 but is sparse until the past decade. Most of the ages are also from 2008 onward. This limits the ability of the model to estimate any changes composition of the population during the majority of the history of the fishery. Estimates of discard rates and mean body weight of discards are available for the years 2002 onward and discard length compositions are available starting in 2010.

The age and length data provide evidence for growth patterns and sex-specific differences in selectivity that are unusual among groundfish stocks that have been assessed within the U.S. West Coast and are not found in Longnose Skate where the data show little difference between the sexes. Growth appears to be almost linear and similar between females and males up to about age 7 or over 100 cm at which point male growth appears to stabilize while females continue to grow. However, in spite of the similar growth pattern for ages prior to 7, males are observed more frequently, with the 70–100 cm length bins often showing 60% males. Sex-specific differences in selectivity were included in the model in order to better match patterns in the sex ratios in the length composition data. The length and age data do not cover enough years or show enough evidence of distinct cohorts to reliably estimate deviations in recruitment around the stock-recruit curve.

The scale of the population is not reliably informed by the data due to the combination of surveys that show trends which can't be matched by the structure of the model and length and age data which inform growth and selectivity but provide relatively little information about changes in stock structure over time. Therefore, a prior on catchability of the WCGBT Survey (centered at 0.83) was applied in order to provide more stable results.

Although the assessment model requires numerous simplifying assumptions, it represents an improvement over the simplistic status-quo method of setting management limits, which relies on average survey biomass and an assumption about F_{MSY}. The use of an age-structured model with estimated growth, selectivity, and natural mortality likely provide a better estimate of past dynamics and the impacts of fishing in the future.

Stock Biomass

The 2018 estimated spawning biomass relative to unfished equilibrium spawning biomass is above the target of 40% of unfished spawning biomass at 75.0% (95% asymptotic interval: ± 63.9%-86.0%) (Figure **??**). Approximate confidence intervals based on the asymptotic variance estimates show that the uncertainty in the estimated spawning biomass is high, although even the lower range of the 95% interval for %unfished is above the 40% reference point, and all sensitivity analyses explore also show the stock to be at a high level.

Table b: Recent trend in beginning of the year spawning output and (spawning biomass relative to unfished equilibrum spawning biomass)

Year	Spawning Output (mt)	˜ 95% confidence interval	Estimated %unfished	˜ 95% confidence interval
2010	1603.690	(726.67-2480.71)	0.721	(0.6-0.842)
2011	1617.560	(738.18-2496.94)	0.727	(0.608-0.847)
2012	1625.610	(745.16-2506.06)	0.731	(0.613-0.849)
2013	1634.790	(753.17-2516.41)	0.735	(0.618-0.852)
2014	1657.340	(772.22-2542.46)	0.745	(0.631-0.859)
2015	1657.020	(772.35-2541.69)	0.745	(0.632-0.859)
2016	1659.820	(774.79-2544.85)	0.746	(0.634-0.859)
2017	1652.180	(768.4-2535.96)	0.743	(0.63-0.856)
2018	1655.400	(770.86-2539.94)	0.744	(0.632-0.857)
2019	1667.190	(780.42-2553.96)	0.750	(0.639-0.86)

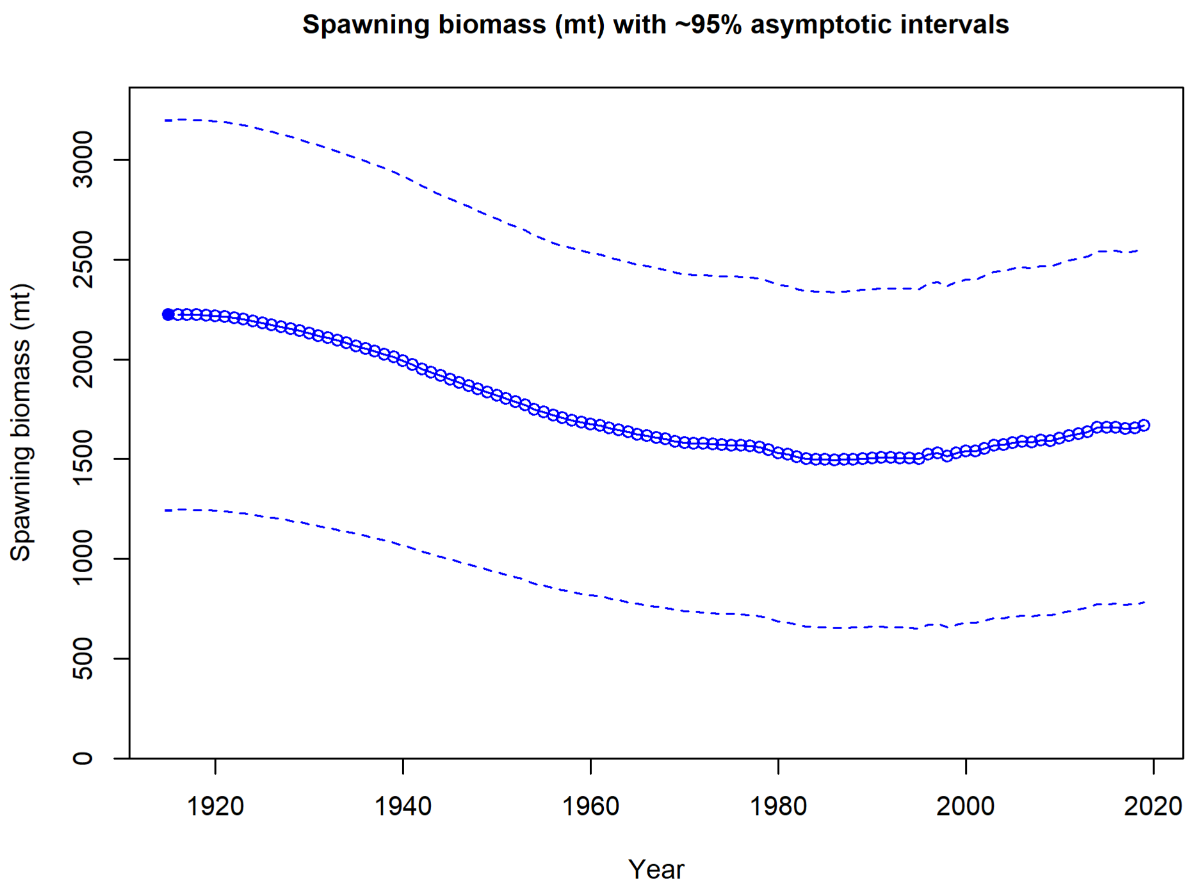

Figure c: Time series of spawning biomass trajectory (circles and line: median; light broken lines: 95% credibility intervals) for the base case assessment model.

Recruitment

Recruitment was assumed to follow the Beverton-Holt stock recruit curve, so uncertainty in estimated recruitment is due to uncertainty in spawning biomass and the unfished equilibrium recruitment R_0 (Figure d and Table c).

Table c: Recent recruitment for the model.

Year	Estimated Recruitment (1,000s)	˜ 95% confidence interval
2010	5393.54	(2966.19 - 9807.3)
2011	5414.62	(2982.16 - 9831.17)
2012	5426.77	(2991.46 - 9844.65)
2013	5440.55	(3002 - 9859.94)
2014	5474.01	(3027.33 - 9898.09)
2015	5473.54	(3027.82 - 9894.77)
2016	5477.66	(3031.98 - 9896.09)
2017	5466.40	(3024.88 - 9878.58)
2018	5471.15	(3029.62 - 9880.26)
2019	5488.48	(3043.55 - 9897.46)

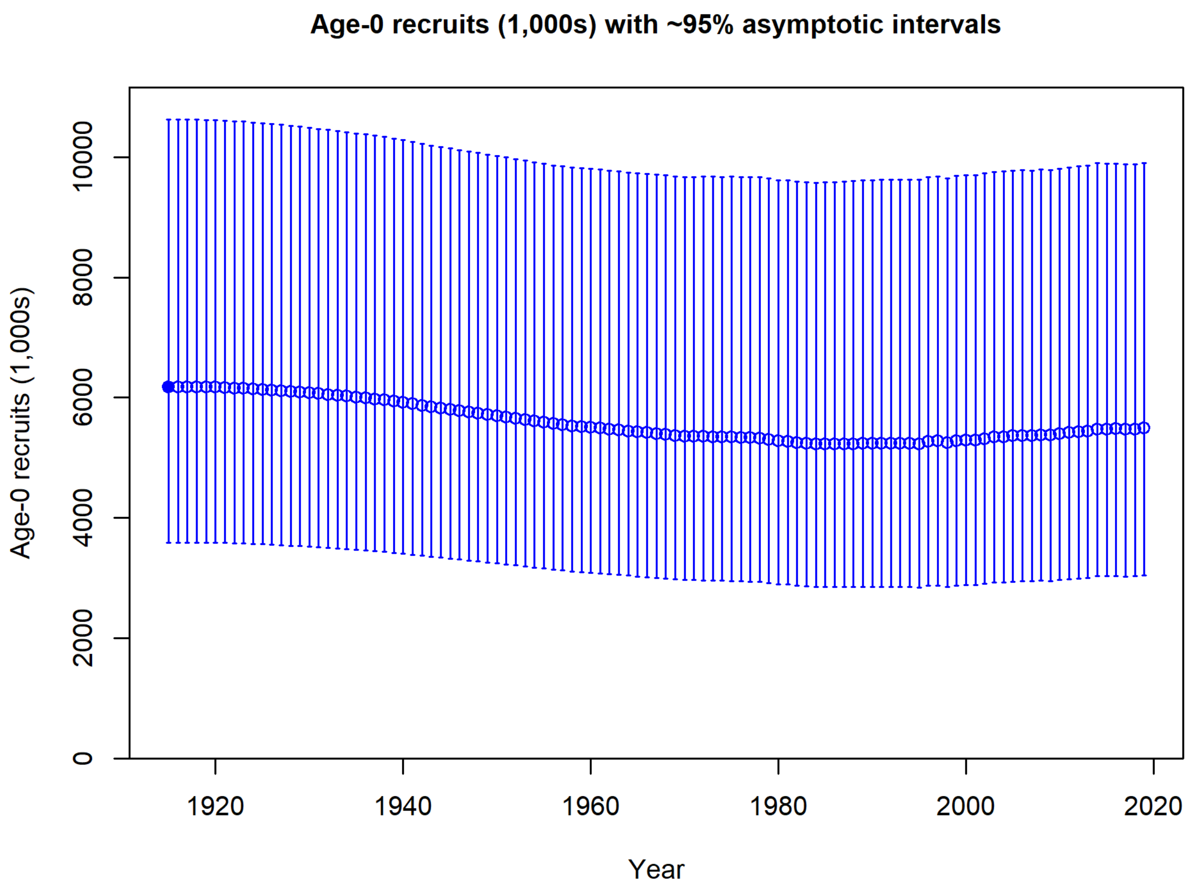

Figure d: Time series of estimated Big Skate recruitments for the base-case model with 95% confidence or credibility intervals.

Exploitation Status

Harvest rates estimated by the base model indicate catch levels have been below the limits that would be associated with the SPR = 50% target (Table d and Figure e).

Table d: Recent trend in spawning potential ratio and exploitation for Big Skate in the model. Relative fishing intensity is (1-SPR) divided by 50% (the SPR target) and exploitation is catch divided by age 2+ biomass.

Year	Relative fishing intensity	~ 95% confidence interval	Exploitation rate	~ 95% confidence interval
2009	0.21	(0.12-0.3)	0.01	(0.01-0.02)
2010	0.20	(0.11-0.29)	0.01	(0.01-0.02)
2011	0.26	(0.15-0.38)	0.01	(0.01-0.02)
2012	0.26	(0.15-0.38)	0.01	(0.01-0.02)
2013	0.14	(0.08-0.2)	0.01	(0-0.01)
2014	0.36	(0.21-0.5)	0.02	(0.01-0.03)
2015	0.32	(0.19-0.45)	0.02	(0.01-0.03)
2016	0.39	(0.23-0.55)	0.02	(0.01-0.03)
2017	0.28	(0.16-0.39)	0.02	(0.01-0.02)
2018	0.18	(0.1-0.25)	0.01	(0.01-0.01)

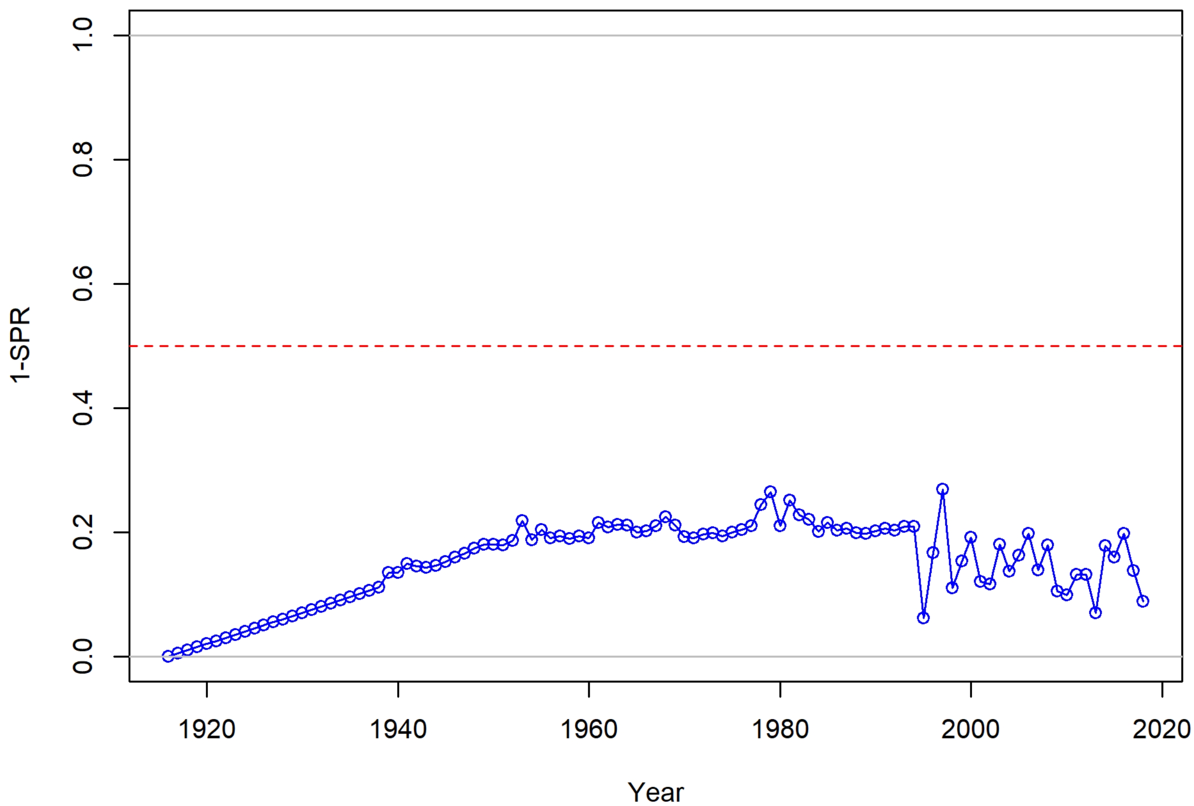

Figure e: Estimated spawning potential ratio (SPR) for the base-case model. One minus SPR is plotted so that higher exploitation rates occur on the upper portion of the y-axis. The management target is plotted as a red horizontal line and values above this reflect harvests in excess of the overfishing proxy based on the $SPR_{50\%}$ harvest rate. The last year in the time series is 2018.

Reference Points

This stock assessment estimates that Big Skate in the model is above the biomass target ($SB_{40\%}$), and well above the minimum stock size threshold ($SB_{25\%}$). The estimated %unfished level for the base model in 2019 is 75.0% (95% asymptotic interval: ± 63.9%-86.0%, corresponding to an unfished spawning biomass of 1667.19 mt (95% asymptotic interval: 780.42-2553.96 mt) of spawning biomass in the base model (Table e). Unfished age 1+ biomass was estimated to be 2,523 mt in the base case model. The target spawning biomass ($SB_{40\%}$) is 890 mt, which corresponds with an equilibrium yield of 602 mt. Equilibrium yield at the proxy F_{MSY} harvest rate corresponding to $SPR_{50\%}$ is 507 mt (Figure f).

Table e: Summary of reference points and management quantities for the base case model.

Quantity	**Estimate**	**Low 2.5% limit**	**High 2.5% limit**
Unfished spawning output (mt)	2,224	1,246	3,202
Unfished age 1+ biomass (mt)	2,523	1,705	3,341
Unfished recruitment (R_0)	6,176	2,760	9,592

Exploitation rate at MSY	0.051	0.045	0.057
Dead Catch MSY (mt)	604	396	812
Retained Catch MSY (mt)	559	367	750

Ecosystem Considerations

In this assessment, neither environmental nor ecosystem considerations were explicitly included in the analysis. This is primarily due to a lack of relevant data or results of analyses that could contribute ecosystem-related quantitative information for the assessment.

Management Performance

Table f: Recent trend in total catch (mt) relative to the management guidelines. Big skate was managed in the Other Species complex in 2013 and 2014, designated an Ecosystem Component species in 2015 and 2016, and managed with stock-specific harvest specifications since 2017.

Year	OFL (mt; ABC prior to 2011)	ABC (mt)	ACL (mt; OY prior to 2011)	Estimated total catch (mt)
2009				205.70
2010				196.20
2011				268.40
2012				269.60
2013	458.00	317.90	317.90	135.00
2014	458.00	317.90	317.90	372.40

1 Fishery Data

1.1 Data

Data used in the Big Skate assessment are summarized in Figure 1. Descriptions of the data sources are in the following sections.

1.2 Fishery Landings and Discards

Catch information for Big Skate is very limited, in part because the requirement to sort landings of Big Skate in the shore-based Individual Fishing Quota fishery from landings in the "Unidentified Skate" category was not implemented until June 2015. The historical catch of Big Skate therefore relies on the historical reconstruction of the landings of all skates as well as an analysis of discards of Longnose Skate. The estimated landings for each state and the tribal fishery are provided in Table 1 and shown in Figure 3.

1.2.1 Washington Commercial Skate Landings Reconstruction

Estimates of landings of Big Skate in Washington state were estimated as a fraction of total skate landings as described in (Gertseva, V. 2019). The approached relied on trawl survey estimates of depth distributions for each species, combined with logbook estimates of fishing depths in each year.

The WCGBT Survey data was used to estimate proportions of longnose and big skates by depth (aggregated into 100m bins) and year for the period of the survey (between 2003 and 2018). Big Skate were primarily found in the 0–100m and 100–200m. Trawl logbook data include information on the amount of retained catch of skate (all species combined) within each haul as well depth of catch. The proportion of Big Skate for each depth bin was assigned to the skate catch for each haul within those depth bins and summed to get a total for each year. When survey skate information was available (2003-2018), survey skate proportions were applied by depth and year to account for inter-annual variability in those proportions. Prior to 2003, average proportions from 2003-2007 within each depth bin were applied.

These estimated annual proportion of Big Skate relative to all skates from the logbook analysis was then applied to total Washington skate landings by year (provided by WDFW) to account for landings that weren't included in the available logbook data. Prior to 1987 (when no logbook data were available), the average proportion Big Skate within the combined skate category, calculated from 1987-1992 logbook data, was applied to total skate landings in Washington. Estimated Big Skate landings provided by WDFW were used for the period from 2004 forward.

1.2.2 Oregon Commercial Skate Landings Reconstruction

Oregon Department of Fish and Wildlife (ODFW) provided newly reconstructed commercial landings for all observed skate species for the 2019 assessment cycle (1978 – 2018). In addition, the methods were reviewed at a pre-assessment workshop. Historically, skates were landed as a single skate complex in Oregon. In 2009, longnose skates were separated into their own single-species landing category, and in 2014, big skates were also separated. The reconstruction methodology differed by these three time blocks in which species composition collections diverged (1978 – 2008; 2009 – 2014; 2015 – 2018).

Species compositions of skate complexes from commercial port sampling are available throughout this time period but are generally limited, which precluded the use of all strata for reconstructing landings. Quarter and port were excluded, retaining gear type, PMFC area, and market category for stratifying reconstructed landings within the three time blocks. Bottom trawl gear types include multiple bottom trawl gears, and account for greater than 98% of skate landings . Minor gear types include primarily bottom longline gear, but also include mid-water trawl, hook and line, shrimp trawl, pot gear and scallop dredge.

For bottom trawl gears, trawl logbook areas and adjusted skate catches were matched with strata-specific species compositions. In Time Block 1 (1978 – 2008), all bottom trawl gear types were aggregated due to a lack of specificity in the gear recorded on the fish tickets. However, in Time Blocks 2 and 3, individual bottom trawl gear types were retained. Some borrowing of species compositions was required (31% of strata) and when necessary, borrowed from the closest area or from the most similar gear type . Longline gear landings were reconstructed in a similar fashion as to bottom trawl and required some borrowing among strata as well (25%).

Due to insufficient species compositions, mid-water trawl landings were reconstructed using a novel depth-based approach. Available compositions indicate that the proportion by weight of big skates within a composition drops to zero at approximately 100 fathoms, and an inverse relationship is observed for longnose skate, where the proportion by weight is consistently one beyond 100 – 150 fathoms . Complex-level landings were assigned a depth from logbook entries and these species specific depth associations were used to parse out landings by species. The approach differed somewhat by time block . Landings from shrimp trawls were handled using a similar methodology. Finally, very minor landings from hook and line, pot gear and scallop dredges were assigned a single aggregated species composition, as they lack any gear-specific composition samples. Landings from within a time block were apportioned by year using the proportion of the annual ticket landings.

Results indicate that the species-specific landings from this reconstruction are very similar to those from Oregon's commercial catch reconstruction (Karnowski et al. 2014) during the overlapping years but cover a greater time period with methodology more applicable to skates in particular. ODFW intends to incorporate reconstructed skate landings into PacFIN in the future (A. Whitman, ODFW; pers. comm.).

1.2.3 California Catch Reconstruction

A reconstruction of historical skate landings from California waters was developed for the 1916–2017 time period using a combination of commercial catch data (spatially explicit block summary catches and port sample data from 2009-2017) and fishery-independent survey data (Bizzarro, J. 2019). Virtually all landings in California were of "unspecified skate" until species-composition sampling of skate market categories began in 2009.

From 2009 through 2017, catch estimates were based on these market category species-composition samples, and the average of those species-compositions was hindcast to 2002, based on the assumption that those data were representative of the era of large area closures in the post-2000 period.

For the period from 1936-1980, spatially explicit landings data (the California Department of Fisheries and Wildlife (CDFW) block summary data) were merged with survey data to provide species-specific estimates.

For years 1981-2001, a "blended" product of these two approaches was taken, in which a linear weighting scheme blended the two sets of catch estimates through that period. Landings estimates were also scaled upwards by an expansion factor for skates landed as "dressed" based on fish ticket data. Prior to 1981 these data had not been reported and skate landings were scaled by the "average" percentage landed as dressed in the 1981-1985 time period, but by the late 1980s nearly all skates were landed round.

As no spatial information on catch is available from 1916-1930, and the block summary data were very sparse in the first few years of the CDFW fish ticket program (1931–1934), spatial information from the late 1930's was used to hindcast to the 1916–1935 time period. However, since Washington and Oregon did not have catch estimates for this year period, the California estimates of catch prior to 1938 were not used as they were subsumed into an estimated of the total catch across all states increasing linearly from 1916 to 1950.

1.2.4 Tribal Catch in Washington

Tribal catch of Big Skate was provided by WDFW as all landings took place in Washington State. The landings were estimated from limited state sampling of species compositions in combined skate category. Anecdotal evidence suggest that most of the catch in tribal fishery is retained, and discard is minimal.

1.2.5 Fishery Discards

Fishery discards of Big Skate are highly uncertain. The method used to estimate discards for Longnose Skate was based on a strong correlation ($R^2 = 95.7\%$) between total mortality of that species, and total mortality of Dover Sole for the years 2009–2017 during which Longnose were landed separately from other skates. In contrast, the sorting requirement for Big Skate occurred too recently to provide an adequate range of years for this type of correlation. Furthermore, there is greater uncertainty in the total mortality for the shallow-water species with which Big Skate most often co-occurs, such as Sand Sole and Starry Flounder, than there is for Dover Sole, which has been the subject of recurring stock assessments.

Both what discard rate information is available and anecdotal information from those involved in the fishery for both skate species indicate that discarding for Big Skate and Longnose Skate in the years prior to 1995 were driven by the same market forced and the discard rates were similar. Therefore, the discard rate for Longnose Skate was used as a proxy for the discards of Big Skate in order to estimate Big Skate discards.

The reconstructed landings of Big Skate for the period 1950–1995 had a mean of 63.1 t with no significant trend (a linear model fit to the data increased from 62.8 t in 1950 to 63.5 in 1995. The estimated tribal catch prior to 1995 averaged less than 1 t and was not included in this analysis of Big Skate discards for the years prior to 1995.

The mean discard rate for LN was 92.46%, also with no significant linear trend (the linear fit decreased from 92.8% in 1950 to 92.1% in 1995). An estimate of the mean annual discard amount can therefore be calculated as from the mean discard rate and the mean landings as $\bar{L}/(1-\bar{d})$ where $\bar{L}$ is the mean landings across that time period and $\bar{d}$ is the mean discards (Figure **??**).

Two alternative methods were used to estimate the mean annual discard amount: applying the annual LN discard rates to the annual BS catch, and applying 3-year moving averages of these two quantities. The use of the annual values resulted in an implausibly high degree of annual variability among the estimates, with the most extreme being a spike of 2146.4 in 1979 compared to 1032.7 t the year before and 654.0 the year after. The use of the 3-year moving average dampened this variability and these estimates were retained for a sensitivity analysis (Figure 4).

A discard mortality rate of 50 percent was assumed for all discards, following the assumption used for the Longnose Skate assessment conducted for the U.S. West Coast in 2007 (Gertseva, V and Schrippa, MJ 2007) The same rate has been used for skates in the trawl fishery in British Columbia, based on an approximate average of these reported rates. In 2015, PFMC's Groundfish Management Team (GMT) conducted a comprehensive literature review of skate discard mortality, and concluded that the current assumption regarding Big Skate discard mortality is consistent with existing reported rates for other similar species.

Estimation of discard rates (discards amount relative to total catch) during the period of the West Coast Groundfish Observer Program (WCGOP), which began in 2002, was hindered by the landings of Big Skate primarily occurring in the "unspecified skate" category prior to 2015. Therefore, a discard rate was computed using the combination of Big Skate and unspecified skate under the assumption that the vast majority of the unspecified skates were

Big Skate. A coefficient of variation was calculated for the by bootstrapping vessels within ports because the observer program randomly chooses vessels within ports to be observed. For the years after the catch share program was implemented in 2011, the trawl fishery was subject to 100% observer coverage and discarding is assumed to be known with minimal error (CV = 0.01).

The mean body weight of discarded Big Skates, calculated from the weight and count of baskets of discarded Big Skate, was available for the years 2002–2017.

2 Fishery-Independent Data Sources

2.1 Indices of abundance

2.1.1 Alaska Fisheries Science Center (AFSC) Triennial Shelf Survey

Research surveys have been used since the 1970s to provide fishery-independent information about the abundance, distribution, and biological characteristics of Big Skate. A coast-wide survey was conducted in 1977 (Gunderson, Donald Raymond and Sample, Terrance M. 1980) by the Alaska Fisheries Science Center, and repeated every three years through 2001. The final year of this survey, 2004, was conducted by the NWFSC according to the AFSC protocol. We refer to this as the **Triennial Survey**.

The survey design used equally-spaced transects from which searches for tows in a specific depth range were initiated. The depth range and latitudinal range was not consistent across years, but all years in the period 1980-2004 included the area from 40° 10'N north to the Canadian border and a depth range that included 55-366 meters, which spans the range where the vast majority of Big Skate encountered in all trawl surveys. Therefore the index was based on this depth range. The survey as conducted in 1977 had incomplete coverage and is not believe to be comparable to the later years, and is not used in the index.

2.1.2 Northwest Fisheries Science Center West Coast Groundfish Bottom Trawl Survey

In 2003, the NWFSC took over an ongoing slope survey the AFSC had been conducting, and expanded it spatially to include the continental shelf. This survey, referred to in this document as the "WCGBT Survey" or "WCGBTS", is conducted annually. It uses a random-grid design covering the coastal waters from a depth of 55 m to 1,280 m from late-May to early-October (Bradburn, M.J. and Keller, A.A and Horness, B.H. 2011 , Keller, A.A. and Wallace, J.R. and Methot, R.D. 2017). Four chartered industry vessels are used each year (with the exception of 2013 when the U.S. federal-government shutdown curtailed the survey).

2.1.3 Index Standardization

The index standardization methods for the two bottom trawl surveys matched that used for Longnose Skate and additional detail is provided in (Gertseva, V. 2019). The data from both surveys was analyzed using a spatio-temporal delta-model (Thorson, J. T. and Shelton, A. O. and Ward, E. J. and Skaug, H. J. 2015), implemented as an R package VAST (Thorson, James T. and Barnett, Lewis A. K. 2017) and publicly available online (https://github.com/James-Thorson/VAST). Spatial and spatio-temporal variation is specifically included in both encounter probability and positive catch rates, a logit-link for encounter probability, and a log-link for positive catch rates. Vessel-year effects were included for each unique combination of vessel and year in the database for the WCGBT Survey but not the Triennial survey. Further details regarding model structure are available in the user manual (https://github.com/James-Thorson/VAST/blob/master/examples/VAST_user_manual.pdf).

Spatial patterns in the survey estimates show Big Skate widely distributed along the coast, with higher densities in the central and more northern areas and closer to shore 7.

2.1.4 Internation Pacific Halibut Commission Longline Survey

The IPHC has conducted an annual longline survey for Pacific Halibut off the coast of Oregon and Washington since 1997 (no surveys were performed in 1998 or 2000). Beginning in 1999, this has been a fixed station design, with 84 locations in this area (station locations differed in 1997, and are therefore not comparable with subsequent surveys). 400 to 800 hooks have been deployed at each station in 100-hook groups (typically called "skates" although that term will be avoided here to avoid confusion). The gear used to conduct the survey was designed to efficiently sample Pacific Halibut and used 16/0 (#3) circle hooks baited with Chum Salmon.

In some years from 2011 onward, additional stations were added to the survey to sample Yelloweye Rockfish. These stations were excluded from the analysis, as were additional stations added in 2013, 2014, and 2017, off the coast of California (south of 42 degrees latitude). Some variability in exact sampling location is practically unavoidable, and leeway is given in the IPHC methods to center the set on the target coordinates while allowing wind and currents to dictate the actual direction in which the gear is deployed. This can result in different habitats being accessed at each fixed deployment location across years. One station that was very close to the U.S. Canada border had the mid-point of the set in Canada in 2 out of the 19 years of the survey. For consistency among years, all samples from this station were included in the analysis, including those in Canada.

In most years, bycatch of non-halibut species has been recorded during this survey on the first 20 hooks of each 100-hook group, although in 2003 only 10% of the hooks were observed for bycatch, and starting in 2012, some stations had 100% of the hooks observed for bycatch. Combining these observation pattern with the number of hooks deployed each year, resulted in most stations having 80, 100, 120, 140, or 160 hooks observed, with a mean of 144 hooks and a maximum of 800 hooks observed. The depth range of the 84 stations considered was 42—530 m, thus extending beyond the range of Big Skate, but 74% of the stations were shallower than 200 m. Big Skate have been observed at 51 of the 84 the standard stations that were retained for this analysis, but no station had Big Skates observed in more than 12 out of the 19 years of survey data, and only 10% of the station/year combinations had at least one observed Big Skate (Figure X). Of those station/year combinations with at least one Big Skate observed, the Big Skates were observed on an average of 1.3% of the hooks observed. The highest proportion was 10 Big Skates out of 81 hooks observed at one station.

The IPHC longline survey catch data were standardized using a Generalized Linear Model (GLM) with binomial error structure. Catch-per-hook was modeled, rather than catch per station due to the variability in the number of hooks deployed and observed each year. The binomial error structure was considered logical, given the binary nature of capturing (or not) a Longnose Skate on each longline hook. The modeling approach is identical to that which has been applied in the past for Yelloweye Rockfish (Stewart et al. 2009), and Spiny Dogfish (Gertseva and Taylor 2011). MCMC sampling of the GLM parameters was used to estimate the variability around each index estimate. The median index estimates themselves were approximately equal to the observed mean catch rate in each year (Figure Y). In recent years, the IPHC standardization of the index of halibut abundance has included an adjustment to account for missing baits on hooks returned empty in an effort to account for reduced catchability of the gear that may result from the lost bait. This adjustment was not included in the analysis for Big Skate although it could be considered in future years.

3 Biological Parameters and Data

3.1 Measurement Details and Conversion Factors

Some size measurements were taken as either disc width or inter-spiracle width rather than total length. A conversion from disc width to total length was estimated as $L = 1.3399 * W$ based on from 95 samples from WCGBT Survey where both measurements collected (R-squared = 0.9983). Little sex difference observed, so using single relationship for both sexes (Figure 15). This estimate is similar to the conversion estimated by Ebert (2008) for Big Skate in Alaska. The inter-spiracle width to total length was converted based on estimates from Downs & Cheng (2013):

$$L = 12.111 + 9.761 * ISW \text{ (females)},$$

$$L = 3.824 + 10.927 * ISW \text{ (males)}.$$

3.2 Fishery dependent length and age composition data

Fishery length composition data was available from PacFIN were available for the years 1995–2018 (with the exception of 2000) as shown in Table 3. Ages were available from only 2004, 2008-2012, and 2018. These were all represented as conditioned on length in order to provide more detailed information about the relationship between age and length, to reduce any influence of size-based selectivity on the age composition, and to ensure independence from the length samples. Furthermore, the samples from Washington in 2009 were sampled using a length-stratified system, so should only be treated as conditioned on length.

Length compositions of Big Skate discarded in commercial fisheries measured by the West Coast Groundfish Observer program were available for the years 2010–2017.

The input sample sizes for the length compositions were calculated via the Stewart Method (Ian Stewart, personal communication, IPHC):

$$\text{Input N} = N_{\text{hauls}} + 0.138 * N_{\text{fish}} \text{ if } N_{\text{fish}}/N_{\text{hauls}} \text{ is} < 44,$$

$$\text{Input N} = 7.06 * N_{\text{hauls}} \text{ if } N_{\text{fish}}/N_{\text{hauls}} \text{ is} \geq 44.$$

However, no haul had greater than 44 Big Skate sampled, so only the first formula was used.

3.3 Survey length and age composition data

Lengths of Big Skate were only collected form the Triennial survey in 1998, 2001, and 2004, but 1998 had only 3 samples and were excluded from this analysis. Length compositions were available for all years of the WCGBT Survey. Sample sizes for both surveys are provided in Table 4. The WCGBT Survey used disc width for the years 2006 and 2007 and total length in all other years. Those samples where only disc width was measured were converted to total length using the formula above.

The length compositions from the fishery and each of the two surveys aggregated across all years is shown in Figure 9.

Ages were available from the WCGBT Survey in the years 2009, 2010, 2016, 2017, and 2018. No ages were available from the Triennial Survey.

Ageing Precision and Bias

Ages of Big Skate were all estimated based on growth band counts of sectioned vertebrae. Ageing precision and bias were estimated using double-reads of 518 Big Skate vertebrae using the approach of Punt et al. (2008). The results showed strong agreement among readers (Figure 13), with a standard deviation of the ageing error increasing from about 0.4 at age 0 to 1.6 years at age 15 (Figure 14).

Weight-Length

The mean weight as a function of length was estimated from 1159 samples from the WCGBT Survey using a linear regression on a log-log scale. Sex was not found to be a significant predictor, so a single relationship was estimated: $Weight = 0.0000074924 * Length^2.9925$ (Figure 15).

Sex Ratio, Maturity, and Fecundity

The female maturity relationship was based on visual maturity estimates from port samplers (n = 278, of which 241 were from Oregon and 37 from Washington, with 24 mature specimens) as well as 55 samples from the WCGBT Survey (of which 4 were mature). The resulting relationship was $L_{50\%} = 148.2453$ with a slope parameter of $Beta = -0.13155$ in the relationship $M = (1 + Beta(L - L_{50\%}))^{-1}$ (Figure 16).

3.4 Environmental or Ecosystem Data Included in the Assessment

In this assessment, neither environmental nor ecosystem considerations were explicitly included in the analysis. This is primarily due to a lack of relevant data or results of analyses that could contribute ecosystem-related quantitative information for the assessment.

4 Assessment

4.1 Previous Assessments

No previous stock assessment has been conducted for Big Skate. The current management is based on an OFL estimate calculated from a proxy for F_{MSY} and average survey biomass from the WCGBT Survey during the years 2010–2012 (Taylor IG and Cope, J and Hamel O and Thorson, J 2013). The F_{MSY} estimate was based on the product of an assumed F_{MSY}/M ratio and an M estimate of 0.162 based on the maximum age of 26 reported by McFarlane and King (McFarlane GA and King JR 2006). Values were sampled from an assumed distribution around all these quantities to develop a measure of uncertainty around the OFL estimate.

4.2 Model Description

4.2.1 Modeling Software

The STAT team used Stock Synthesis version 3.30.13 (Methot, Richard D. and Wetzel, Chantell R. (2013), Methot, RD Jr. and Wetzel, CR and Taylor, IG (2019)). The r4ss package version 1.35.1 (Taylor et al. 2019) was used to post-process the output data from Stock Synthesis.

4.2.2 Summary of Data for Fleets and Areas

Catch is divided among 4 fleets in the base model:

- *Fishery (current)* combines all non-tribal sources of catch for the years 1995 onward,
- *Discard (historical)* includes the estimated discard amount calculated from the estimated Longnose Skate discard rate as described above. The input catch for this fleet was 50
- *Fishery (historical)* includes the reconstructed landings estimates from each of the three states for 1916–1994.
- *Tribal* includes the estimates of catch of Big Skate by treaty tribes.

4.2.3 Other Specifications

This assessment covers the U.S. West Coast stock of Big Skate in off the coasts of Washington, Oregon and California, the area bounded by the U.S.-Canada border to the north, and the U.S.-Mexico border to the south. The population is treated as a single coastwide stock with no net movement in or out of the area. Females and males are modeled separately as there is evidence for differences in growth based on both the age and length data, as well as patterns in the sex ratios associated with the length composition data. Natural Mortality is estimated within the model using natural mortality prior developed by Hamel (2015). A Beverton-Holt stock-recruit function is assumed with no deviations from the spawner-recruit curve estimated.

The length composition data are stratified into 37 5-cm bins, ranging between 20 and 200 cm and the age data are stratified into ages 0–15+, conditioned on the same length bin structure. The population dynamics are computed over a larger range of lengths age ages, with the 5-cm length bins extending up to 250 cm and the numbers-at-age computed up to age 20.

4.2.4 Data Weighting

The Francis (2011) data weighting method "TA1.8" as implemented in the r4ss package was used for all length and age composition data.

4.2.5 Priors

Natural Mortality A log-normal prior for natural mortality was based on a meta-analysis completed by Hamel (2015). The Hamel prior for M is lognormal(ln(5.4/max age), .438), which based on the single 15-year-old fish observed out of 1034 ages from the WCGBT Survey. This results in lognormal(log(0.36) = –1.021651, 0.438) prior.

Survey Catchability The lack of contrast in the data resulted in unstable model results under a variety of configurations. To keep biomass estimates within a plausable range, the assessment uses a prior on the WCGBTS survey catchability parameter (q) that was originally developed for the 2007 Longnose Skate assessment (Gertseva, V and Schrippa, MJ 2007), and is being used for the concurrent Longnose Skate assessment (Gertseva, V. 2019). The prior for the WCGBT Survey was derived as follows.

Several factors inform catchability in the survey. The WCGBT Survey covers the full latitudinal range of Longnose Skate modeled in the assessment, and thus, the latitudinal availability factor was assumed to be one (complete latitudinal coverage). The survey coverage exceeds the maximum depth distribution of Longnose Skates but doesn't fully cover the shallow end of the skate distribution. A range of 95 to 100 percent was assumed for the depth availability. A range of 75 to 95 percent was assumed for vertical availability on the basis that skates are known to bury in the mud, and therefore some may be unavailable to the bottom trawl gear.

The largest bounds were placed on the probability of capture, given that a fish is in the net path. It is known that flatfish can be herded by trawl gear, and it is possible that this could also occur for skates. However, it is also possible that skate could avoid the trawl nets. For capture probability, a range of 75 to 150 percent was assumed. The best estimates for each of these factors were set at the midpoint of the range for individual factors, except for the probability of capture, which was given a value of one. The overall estimate for the survey catchability was thus estimated to be 0.83 with bounds of (0.53, 1.43). The best estimate was converted to the median of a lognormal distribution and the bounds to 99 percent of that distribution. This resulted in a normal prior on $log(q)$, with a mean of –0.188, and standard deviation of 0.187.

4.2.6 Estimated Parameters

A full list of all estimated and fixed parameters is provided in Tables 6.

The base model has a total of 44 estimated parameters in the following categories:

- 1 natural mortality parameter applied to both sexes,
- 6 parameters related to female growth and the variability in **length age age,**
- 2 parameters related to male growth relative to female growth,
- 1 stock-recruit parameter ($log(R_0)$ controlling equilibrium recruitment)
- 3 catchability parameters (1 for the WCGBT Survey and 1 each for the early and late periods of the Triennial Survey)
- 2 extra standard deviation parameters (1 for each survey)
- 29 selectivity parameters, including 16 related to time-varying retention rate

The estimated parameters are described in greater detail below and a full list of all estimated and parameters is provided in Table 6.

Growth. Examination of patterns of age-at-length and length-at-age indicated unusual patterns of growth for Big Skate. The youngest fish show near-linear growth, and average size for both sexes is similar. However, older fish show considerable sex-based differences in size.

This led to the choice to model growth using the "growth cessation model" recently developed by Maunder et al. (2018). The estimated growth curves are shown in Figure 10.3.1. This model provided two key advantages over the more common von Bertalanffy growth model in the case of Big Skate: it allowed essentially linear growth for the early years and it allowed growth for the earlier ages to be similar between females and males while diverging at older ages. The growth cessation model also improve the negative log likelihood by 45 units relative to the von Bertalanffy growth model.

Natural Mortality. Male natural mortality was assumed equal to the value estimated for females. Sensitivity analyses were used to test the impact of both the the prior on natural mortality and the assumption of equal natural mortality for both sexes.

Selectivity.
A double-normal selectivity function was used for all fleets to allow consideration of both asymptotic and dome-shaped patterns. For the fishery and the Triennial survey, the difference in likelihood between dome-shaped and asymptotic patterns was very small and in the case of the Triennial survey, the dome-shape occurred at a length beyond almost all observations, indicating that this shape was likely driven by fit to other data sources, such as the index, rather than the length composition data. The WCGBT Survey was allowed to remain dome-shaped as this survey had the selectivity peak at a smaller length than the other fleets and the likelihood was improved by the dome-shape. The WCGBT Survey also has the shortest hauls, with 15 minutes or less of bottom contact, so larger skates may be better able to escape the net.

In order to fit a strong skew in the sex ratios toward males for the length bins in which the majority of the samples were found, it was necessary to estimate a sex-specific offset of selectivity. Two offset parameters were estimated for all fleets, one for the difference in length at peak selectivity and another for the maximum selectivity. The ascending slope was assumed equal in all cases, as was the descending slope for the WCGBT Survey.

4.2.7 Fixed Parameters

The steepness of the Beverton-Holt stock-recruit curve was fixed at 0.4. The same value was used in the 2007 Longnose Skate assessment (Gertseva, V and Schrippa, MJ 2007) ans is being considered for the ongoing 2019 Longnose Skate assessment. This value reflects a K-type reproductive strategy associated with elasmobranchs in general. The influence of the assumption of $h = 0.4$ on model output was explored via a likelihood profile analysis.

4.3 Model Selection and Evaluation

4.3.1 Key Assumptions and Structural Choices

To be added prior to May 20 CIE pre-review deadline.

4.3.2 Alternate Models Considered

To be added prior to May 20 CIE pre-review deadline.

4.3.3 Convergence

One hundred sets of jittered starting values were generated using the jitter function built into Stock Synthesis, with used with jitter input = 0.1. The same likelihood as the base model was returned by 54 out of the 100 runs, while the others all had worse total likelihood.

4.5 Base Case Model Results

The following description of the model results reflects a base model that incorporates all of the changes made during the STAR panel (see previous section). The base model parameter estimates and their approximate asymptotic standard errors are shown in Table 6 and the likelihood components are in Table 7. Estimates of derived reference points and approximate 95% asymptotic confidence intervals are shown in Table e. Time-series of estimated stock size over time are shown in Table 8.

4.5.1 Parameter Estimates

The additional survey variability (process error added directly to each year's input variability) for all surveys was estimated within the model.

(Figure 29).

The stock-recruit curve ... Figure 30 with estimated recruitments also shown. }}$**

4.5.2 Fits to the Data

Indices. The observed indices show much more variability than the model expectation, with the fit to the WCGBT Survey essentially a flat line (Figure 10.3.2) and the fit to the Triennial Survey only showing a noticeable change over time due to the separate catchability parameter estimated for the early and late periods (Figure 18).

Length Data. The fits to the length data are much better thanks to the combination of the growth cessation model and the sex-specific offsets to selectivity (Figures 19–20).

Conditional Age-at-Length. The conditional age-at-length data is likewise fit reasonably well, with some patterns in residuals showing variability among years, but no clear pattern that is consistent across years (Figures 21 and 22).

Sex Ratios. Sex ratio data is not included in the likelihood as such, but as a part of the length composition likelihood. The proportions of females and males are compiled into a single vector that is compared to the model expectations in the multinomial likelihood. The patterns in sex ratio by length bin show fewer females than males for the middle range of sizes (70–120 cm), with a shift to almost 100% females for the largest size bins (over 130 cm). The use of sex-specific growth curves was adequate to fit the ratios for the largest bins, but ratio skews toward males at lengths where the mean ages are similar for females and males. The fit to this part of the sex ratio pattern required an offset in selectivity.

4.5.3 Uncertainty and Sensitivity Analyses

A number of sensitivity analyses were conducted, including:

1. Setting all selectivity curves to be asymptotic
2. Setting all selectivity curves to be dome-shaped
3. Removing the sex-specific offset on the selectivity curves
4. Removing the prior on catchability for the WCGBT Survey
5. Estimating a single catchability for all years in the Triennial Survey
6. Estimating separate natural mortality parameters for males and females
7. Removing the prior on natural mortality
8. Using the von Bertalanffy growth model
9. Using the Richards growth model
10. Tuning the sample sizes using the McAllister-Ianelli method
11. Estimating historic discards based on 3yr average of discard rates and landings
12. Changeing discard mortality from 0.5 to 0.4
13. Changeing discard mortality from 0.5 to 0.6

Results of these sensitivities are shown in Figures 32 to 34, and Tables 9 to 11.

Additional text to be added

4.5.4 Retrospective Analysis

To be added

4.5.5 Likelihood Profiles

Likelihood profiles were conducted over $log(R_0)$, stock-recruit steepness (h) and natural mortality (M).

Results of these profiles are shown in Figures 37 to 42.

Additional text to be added

4.5.6 Reference Points

Reference points were calculated using the estimated selectivities and catch distribution among fleets in the most recent year of the model, (2017). Sustainable total yield (landings plus discards) were 507 mt when using an $SPR_{50\%}$ reference harvest rate and with a 95% confidence interval of 333 mt based on estimates of uncertainty. The spawning biomass equivalent to 40% of the unfished level $(SB_{40\%})$ was 890 mt.

(Figure 27

The 2018 spawning biomass relative to unfished equilibrium spawning biomass is above/below the target of 40% of unfished levels (Figure **??**). The relative fishing intensity, $(1 - SPR)/(1 - SPR_{50\%})$, has been xxx the management target for the entire time series of the model.

Table e shows the full suite of estimated reference points for the base model and Figure 43 shows the equilibrium curve based on a steepness value xxx.

5 Harvest Projections and Decision Tables

The forecasts of stock abundance and yield were developed using the final base model, with the forecasted projections of the OFL presented in Table g.

The forecasted projections of the OFL for each model are presented in Table h.

6 Regional Management Considerations

7 Research Needs

There are a number of areas of research that could improve the stock assessment for Big Skate. Below are issues identified by the STAT team and the STAR panel:

1. **Data!**:
2. **xxxx**:
3. **xxxx**:
4. **xxxx**:
5. **xxxx**:

8 Acknowledgments

The authors gratefully acknowledge the time and effort reviewers Stacey Miller, Jim Hastie and Owen Hamel put into making this a polished document.

10 Figures

10.1 Data Figures

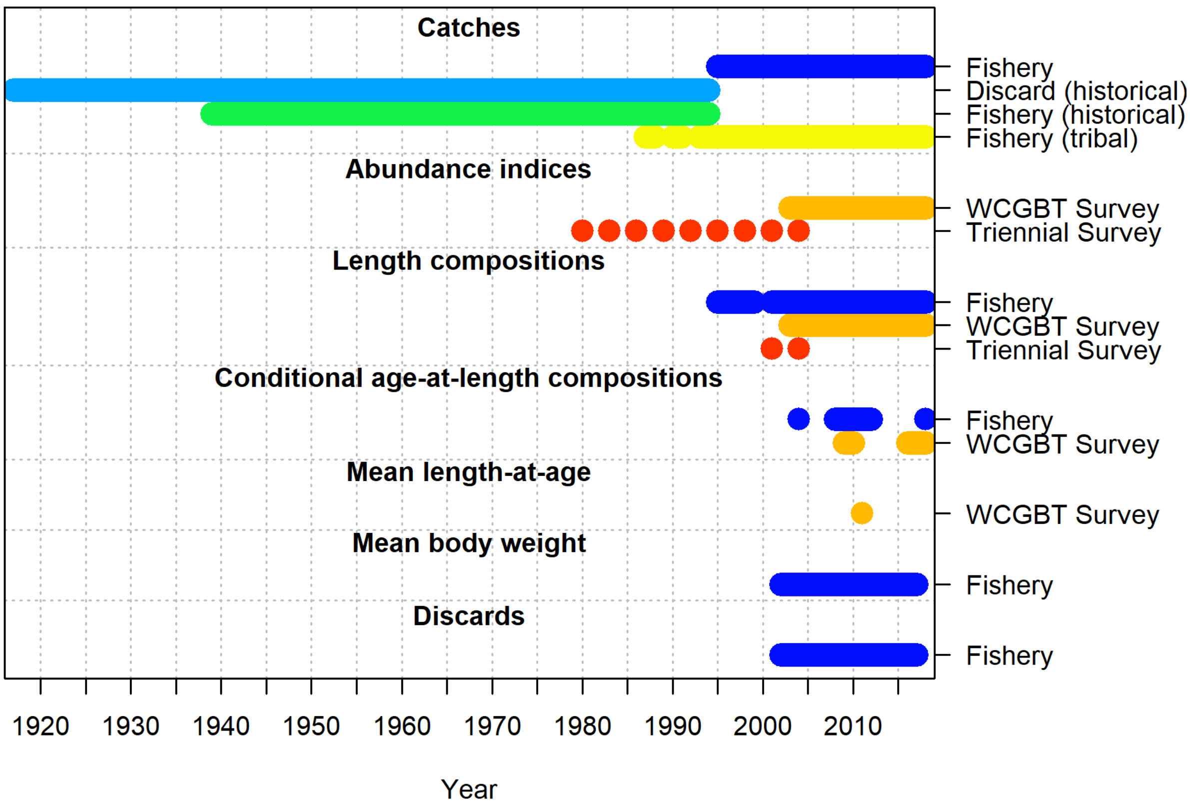

Figure 1: Summary of data sources used in the model.

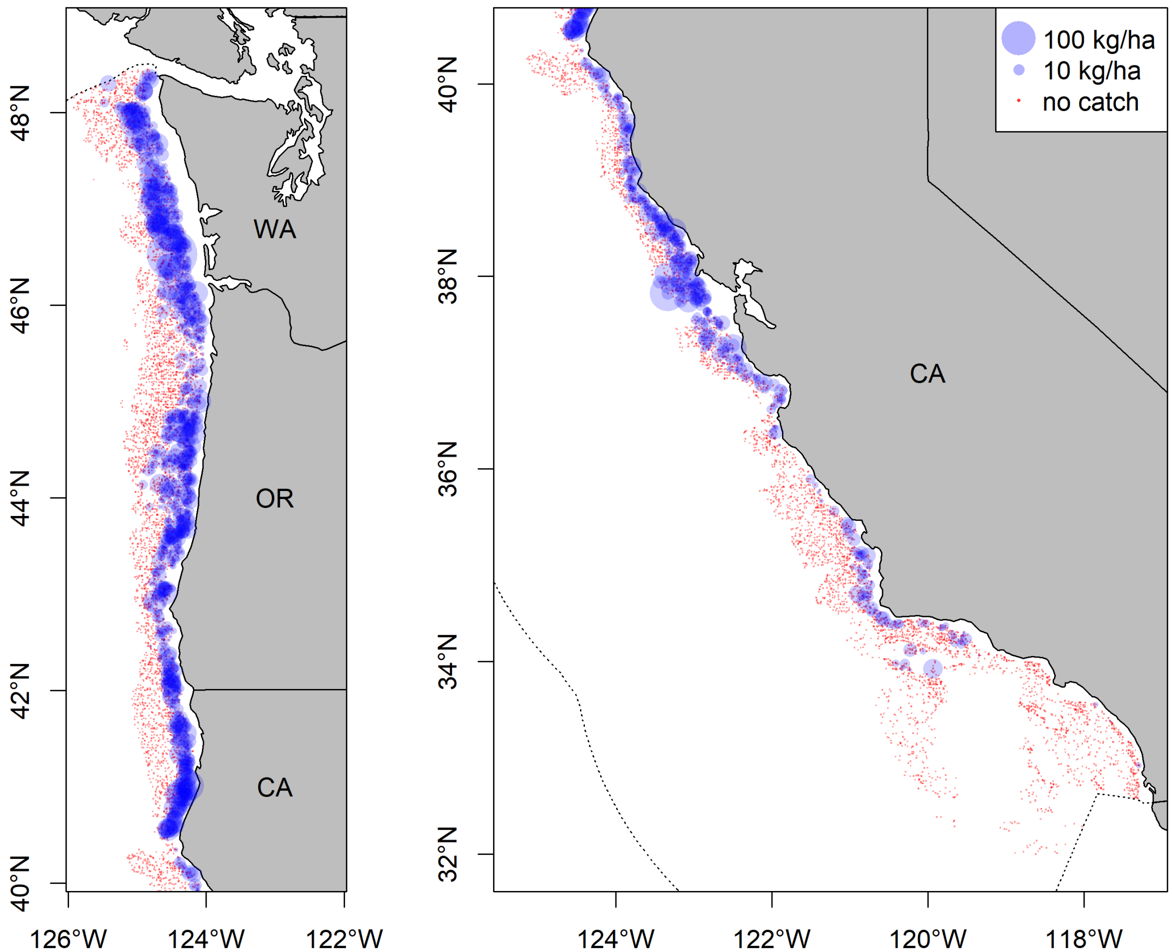

Figure 2: Map showing the distribution of Big Skate within the area covered by the West Coast Groundfish Bottom Trawl Survey aggregated over the years 2003–2018.

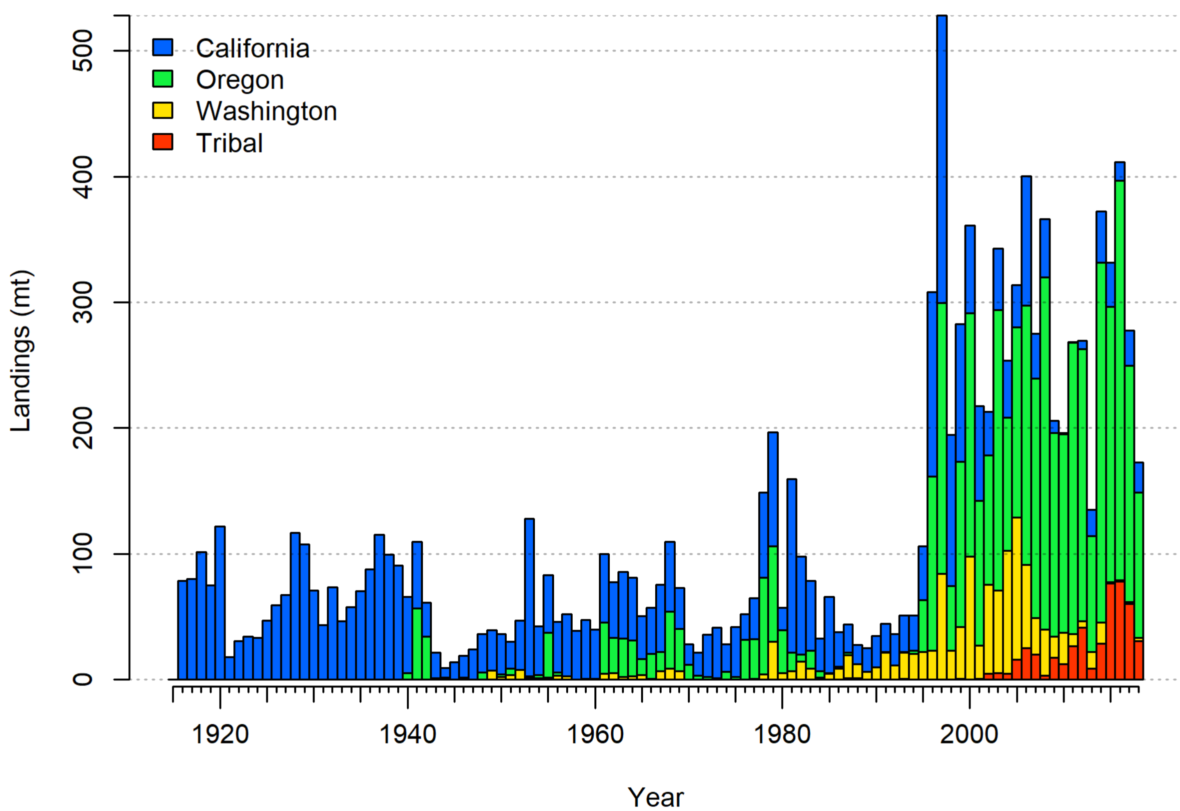

Figure 3: Reconstructed landings by area. Tribal catch was all landed in Washington.

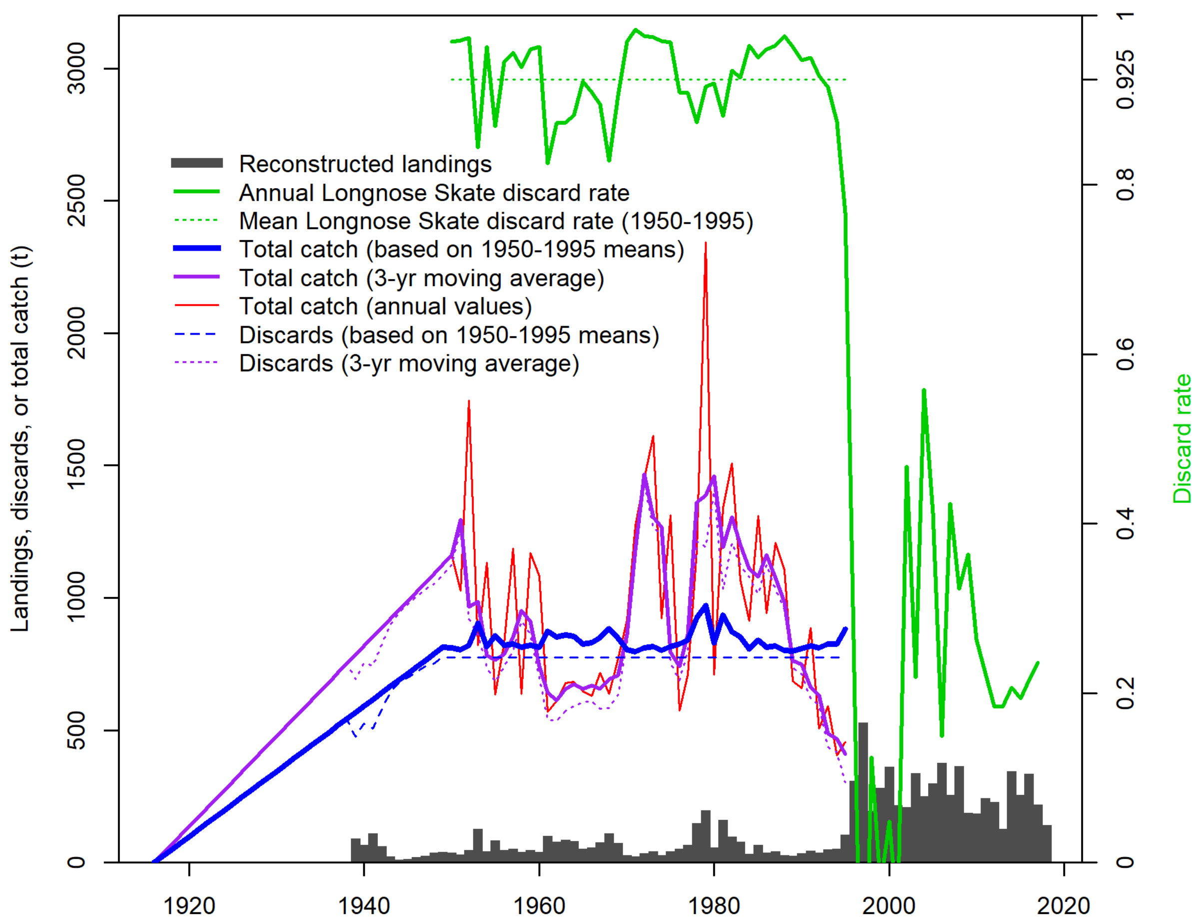

Figure 4: Estimated total catch using different assumptions for discards. The discard rates shown in green lines are relative to the right-hand axis while all other values are relative to the left-hand axis.

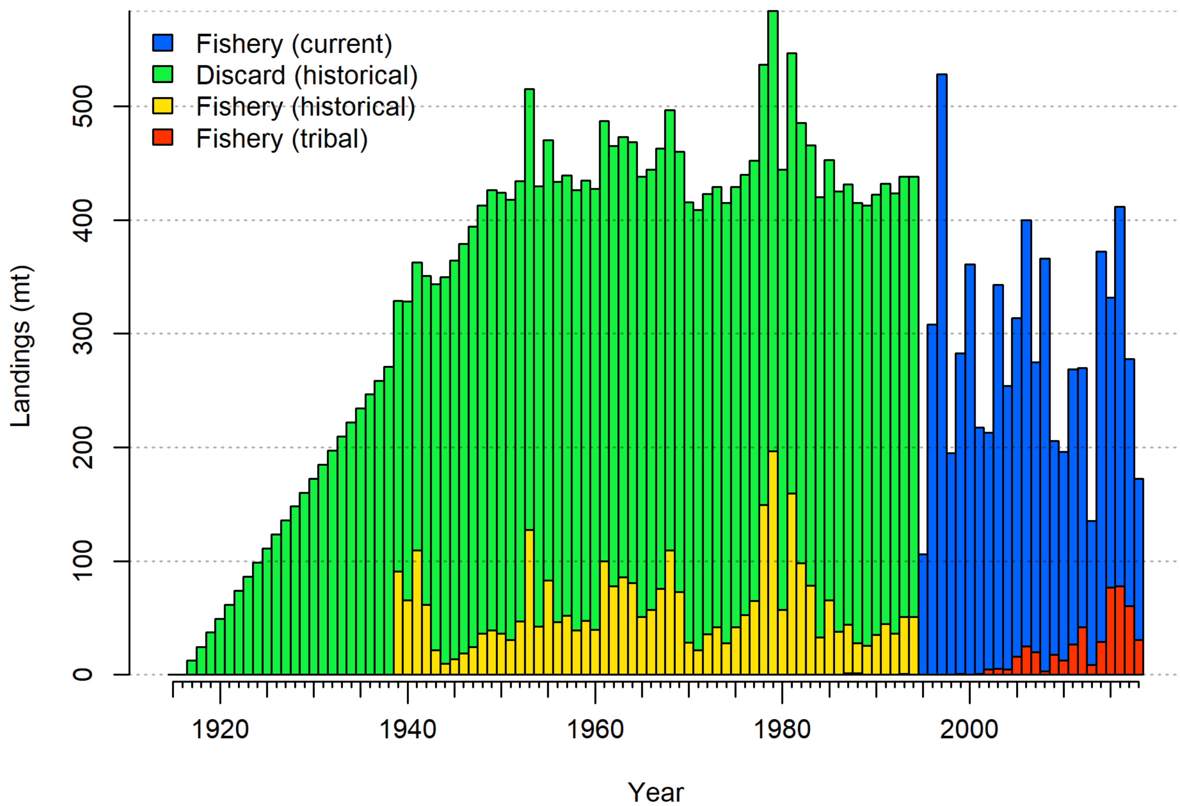

Figure 5: Catch data input to the model under assumed fleet structure. The historical discards shown in green have been scaled to account for an assumed 50% discard mortality. Discards during the period from 1995 onward are not represented here as they are estimated within the model.

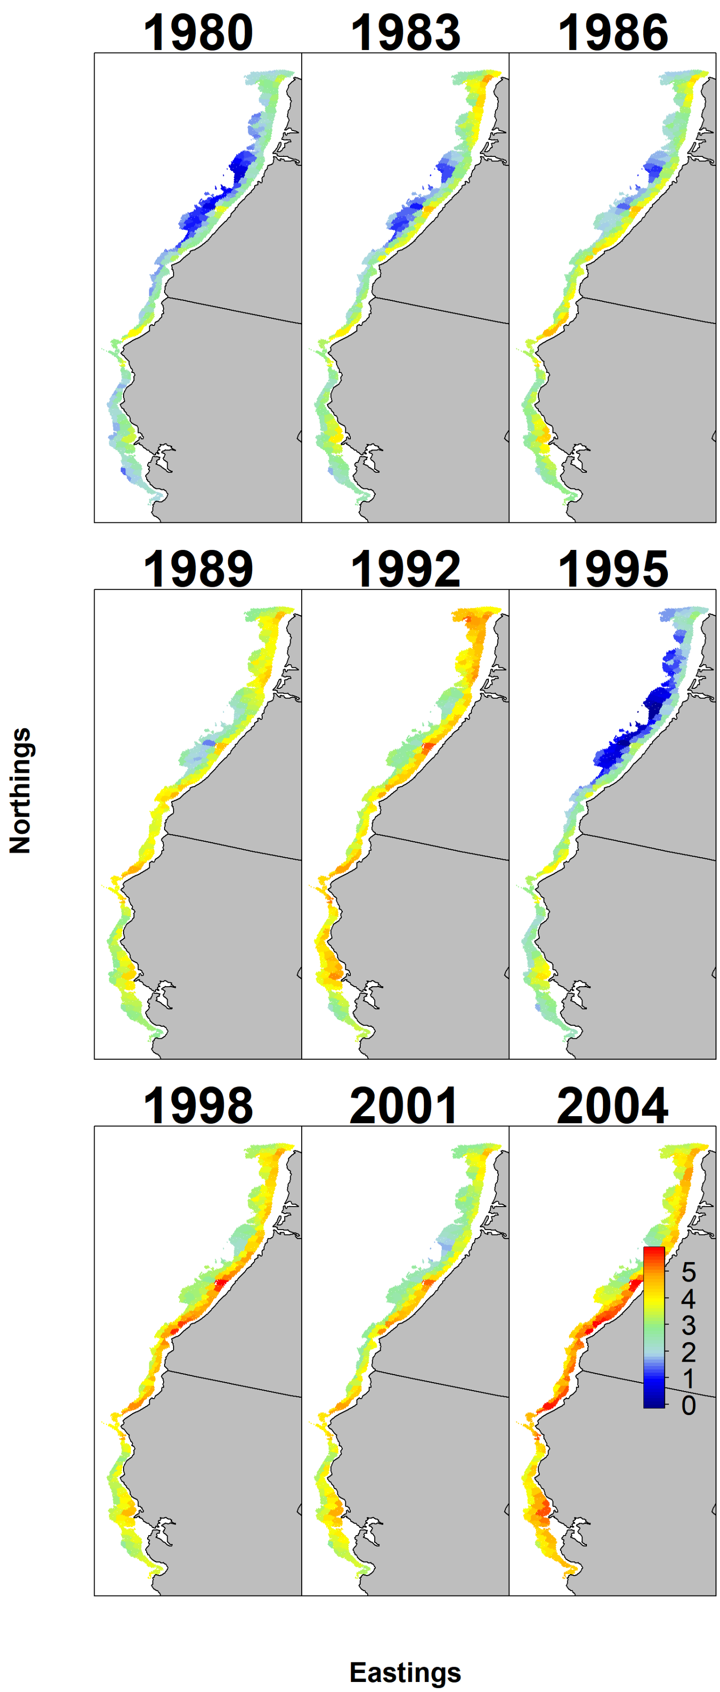

Figure 6: Map of estimated density by year for Big Skate in the Triennial survey.

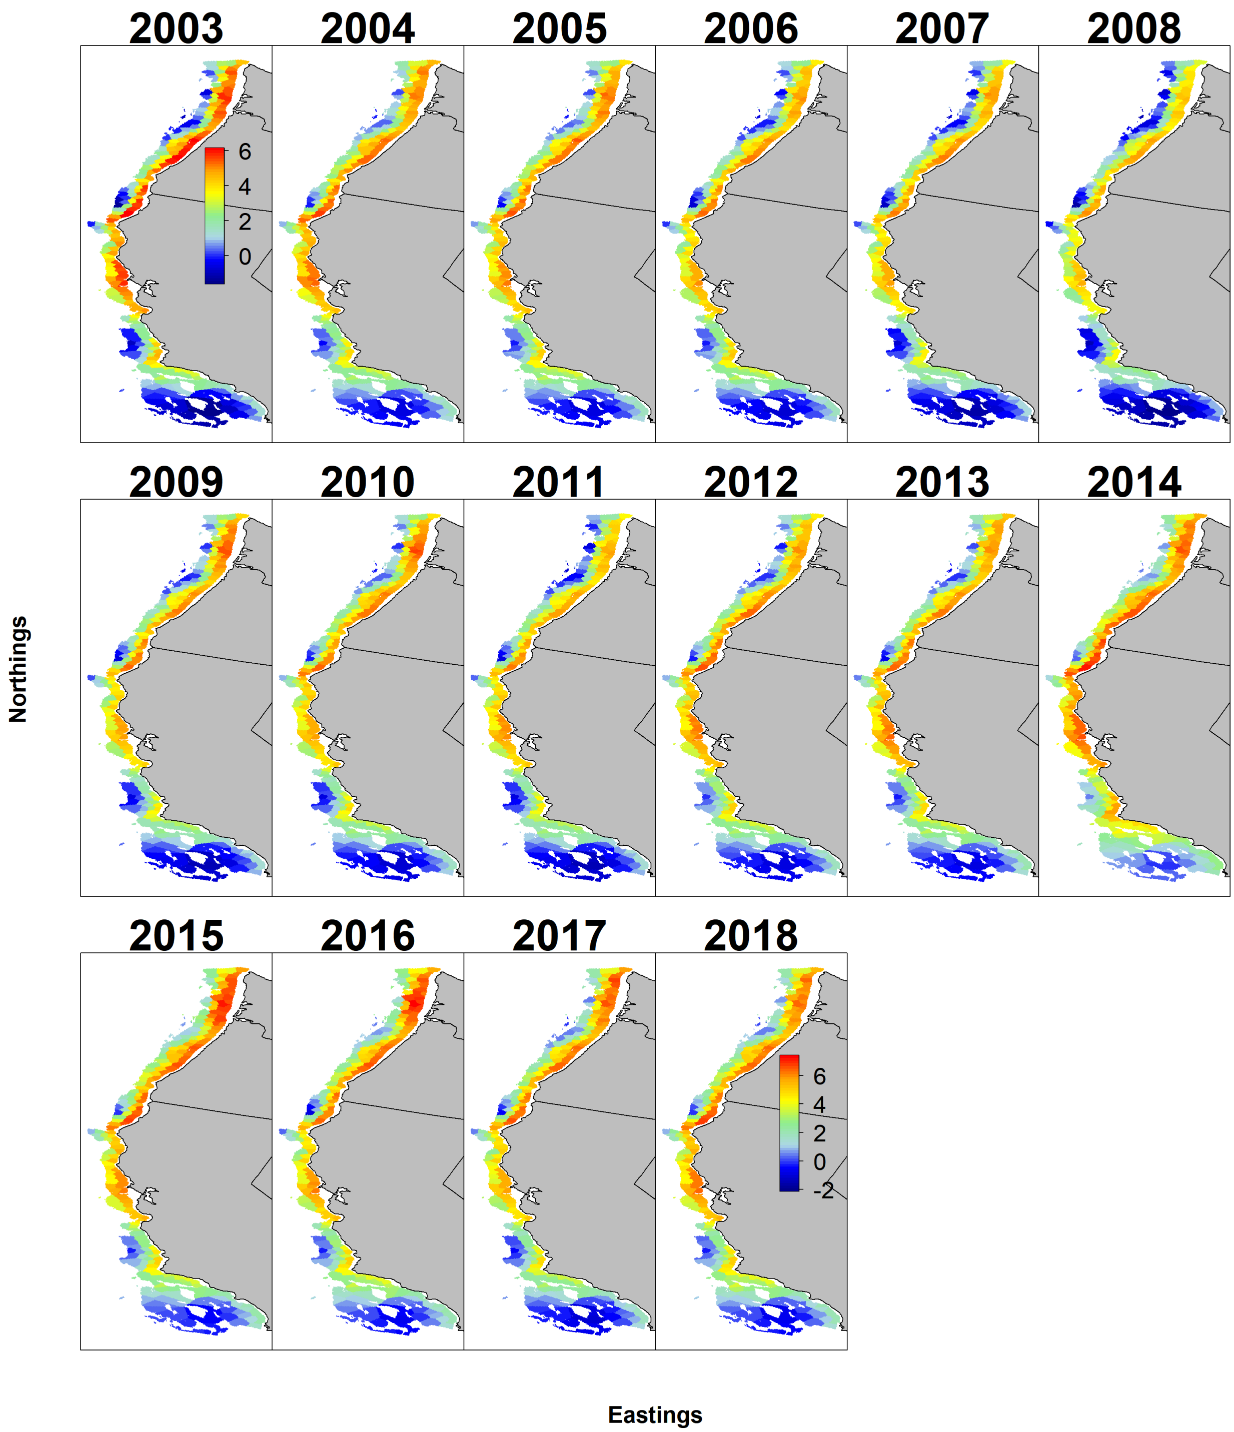

Figure 7: Map of estimated density by year for Big Skate in the WCGBT Survey.

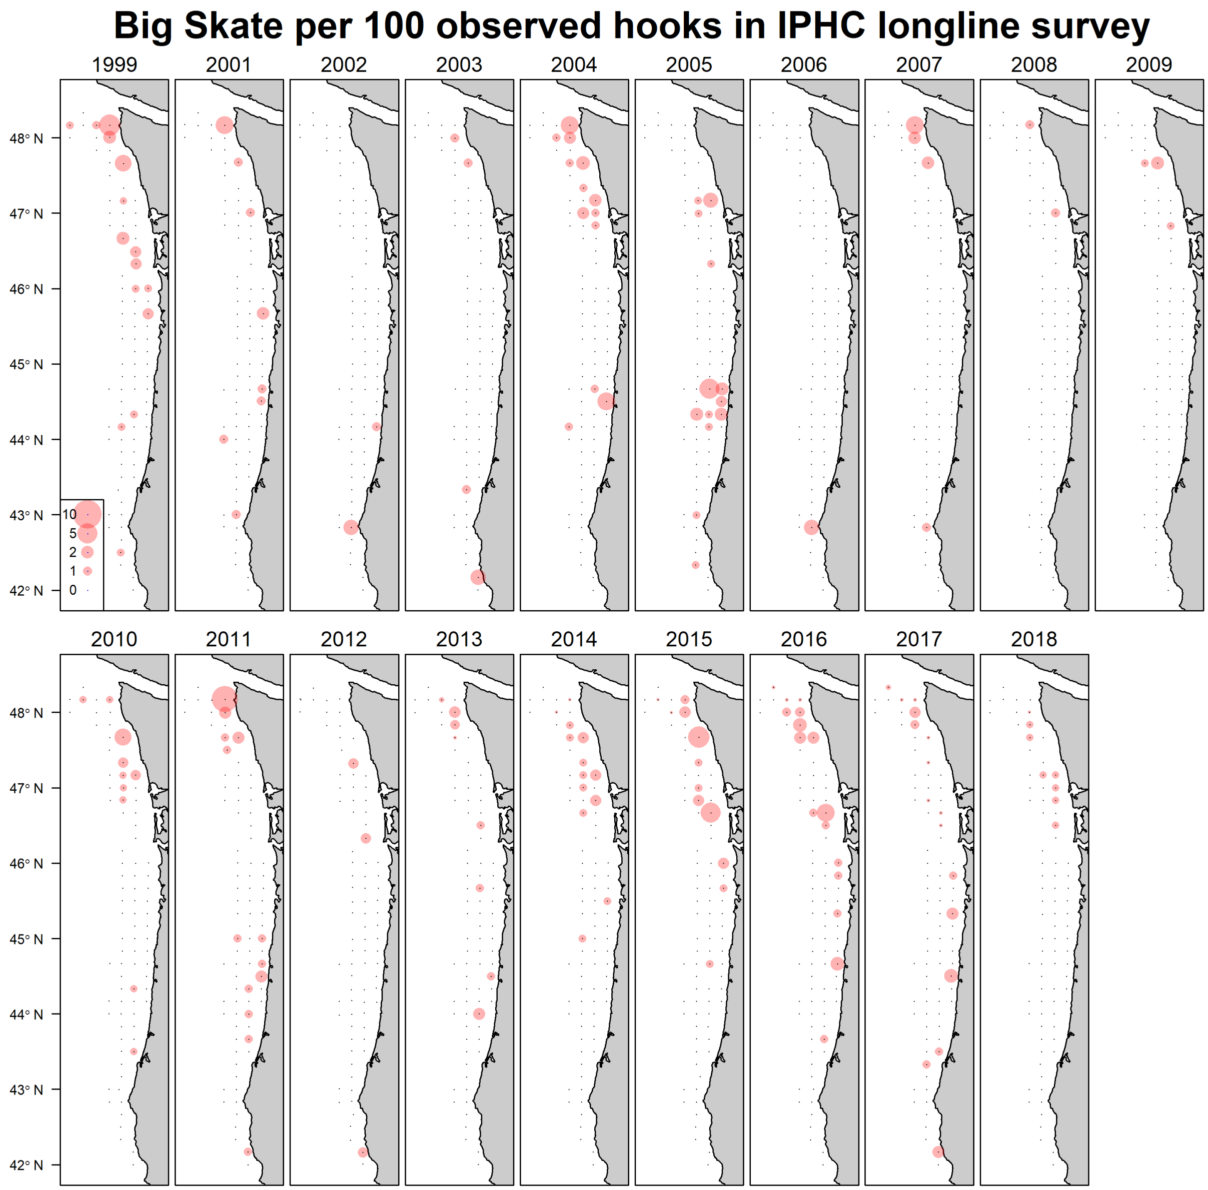

Figure 8: Map of catch rates by year for Big Skate in the International Pacific Halibut Commission longline survey.

739 ## 10.2 Biology Figures

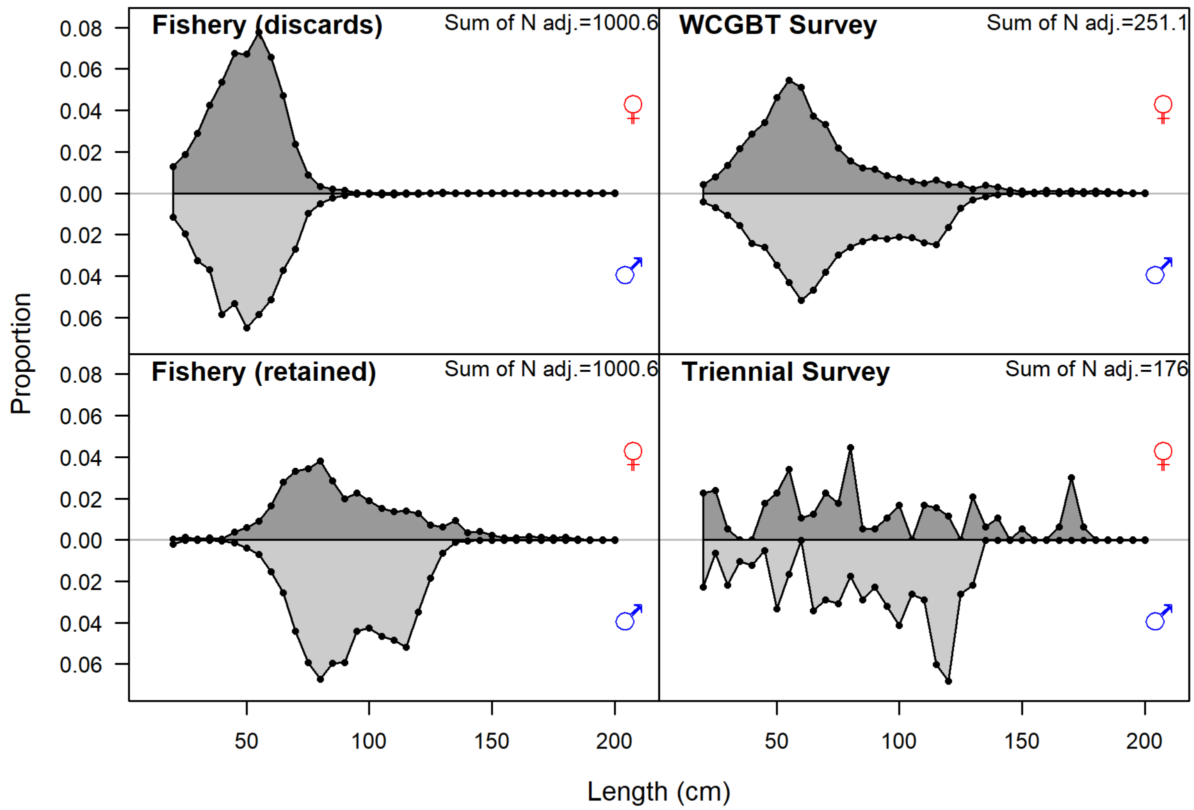

Figure 9: Length comp data, aggregated across time by fleet.

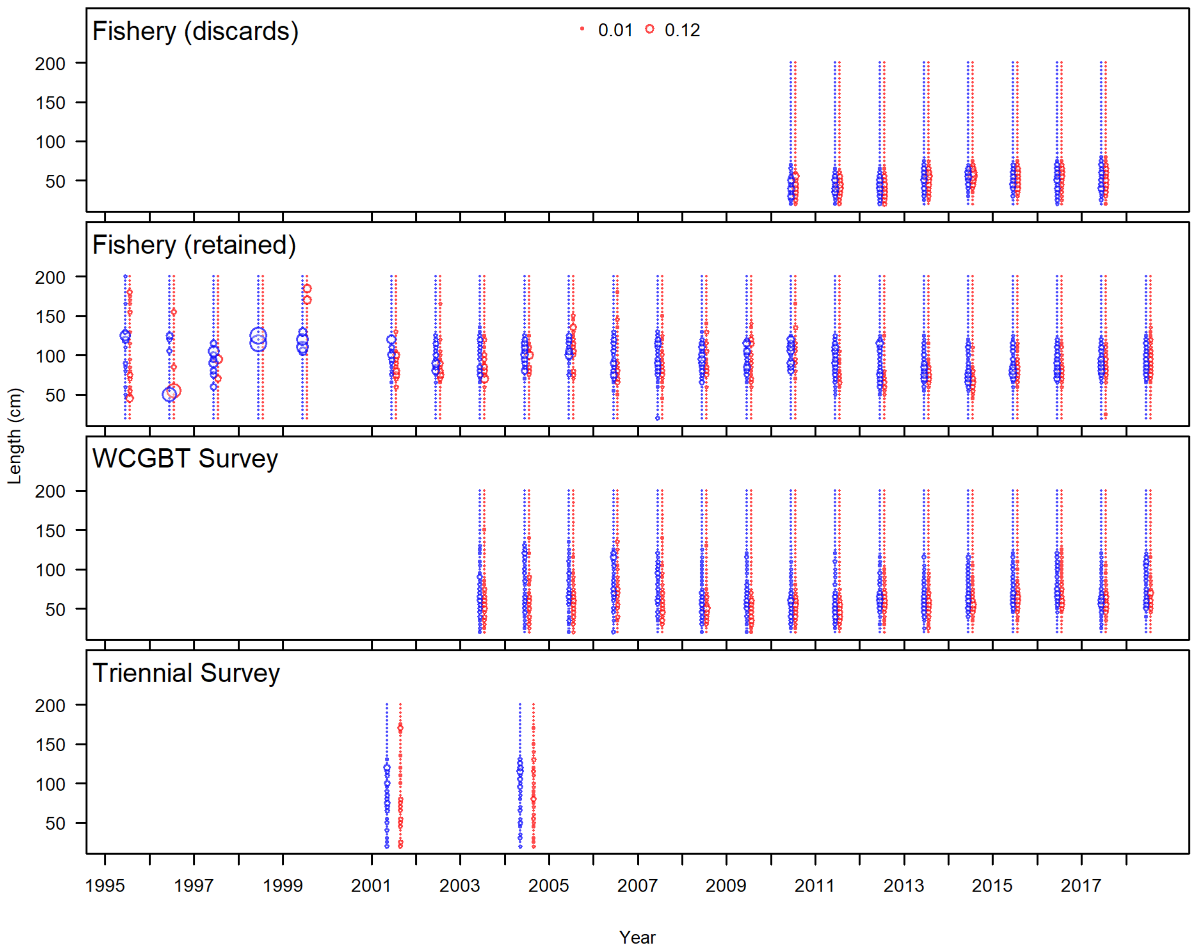

Figure 10: Length comp data for all years and fleets. Bubble size indicates the observed proportions, with females in red and males in blue.

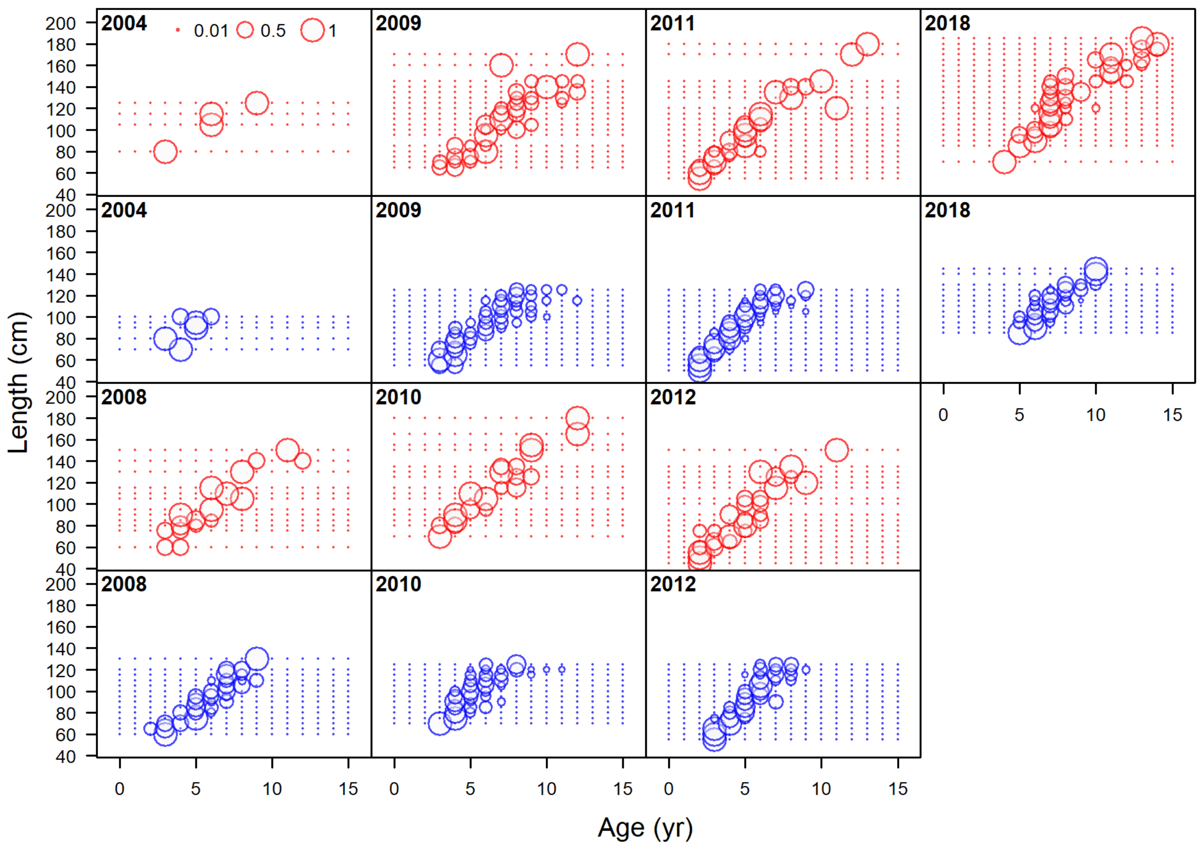

Figure 11: Conditional age-at-length data from the fishery.

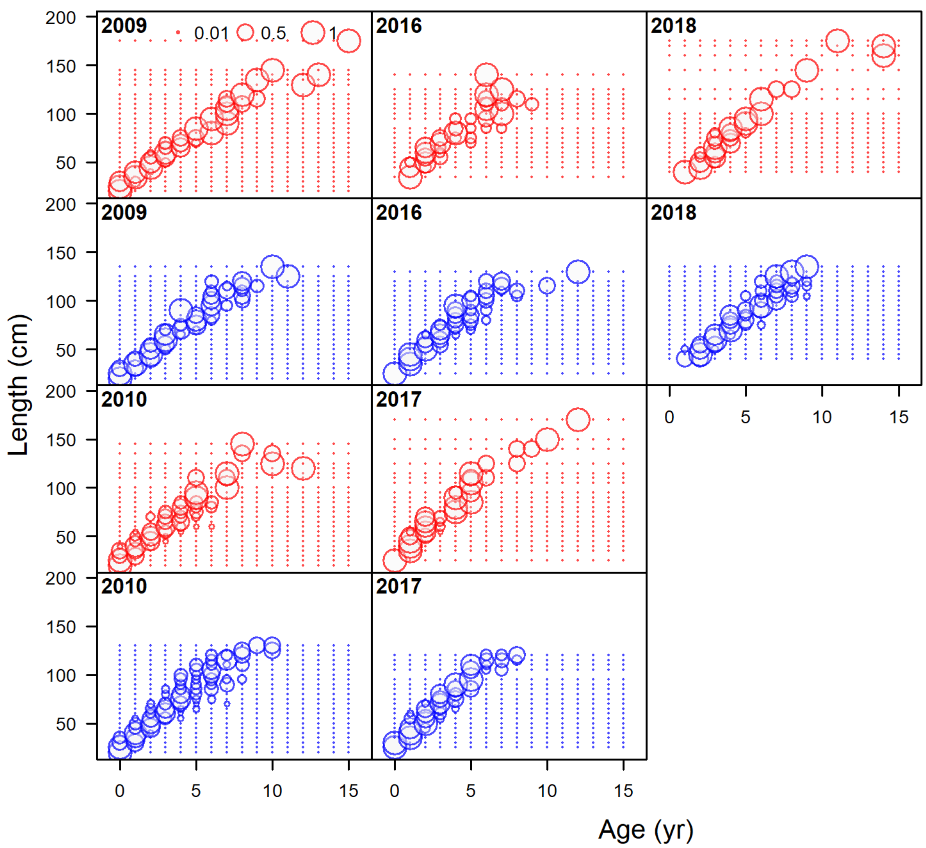

Figure 12: Conditional age-at-length data from the WCGBT Survey.

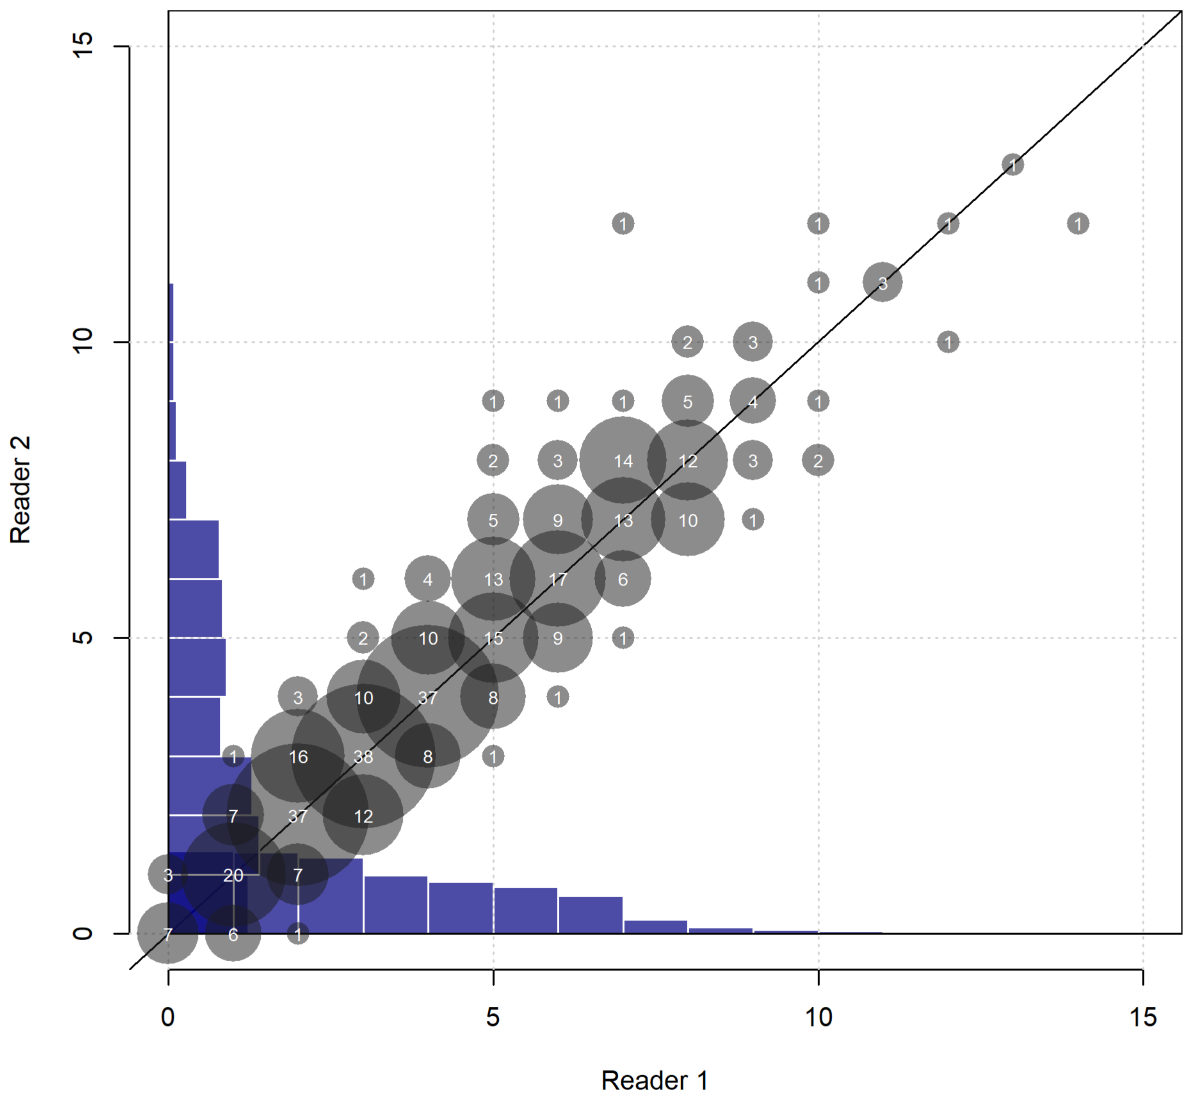

Figure 13: Comparison of reads from each of two age readers for Big Skate. Sample sizes associated with each combination of ages are shown by the size circles and the within them. The blue histograms show the distribution of ages estimated by each reader.

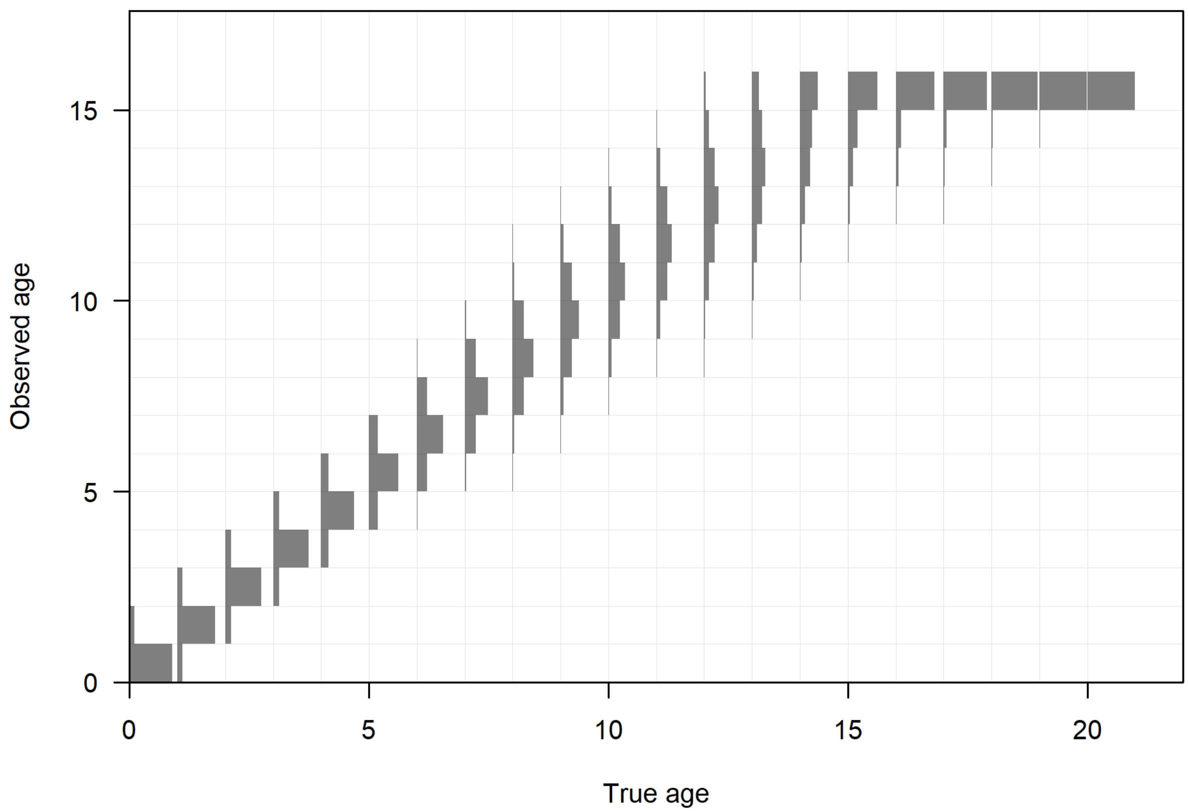

Figure 14: Estimated ageing imprecision.

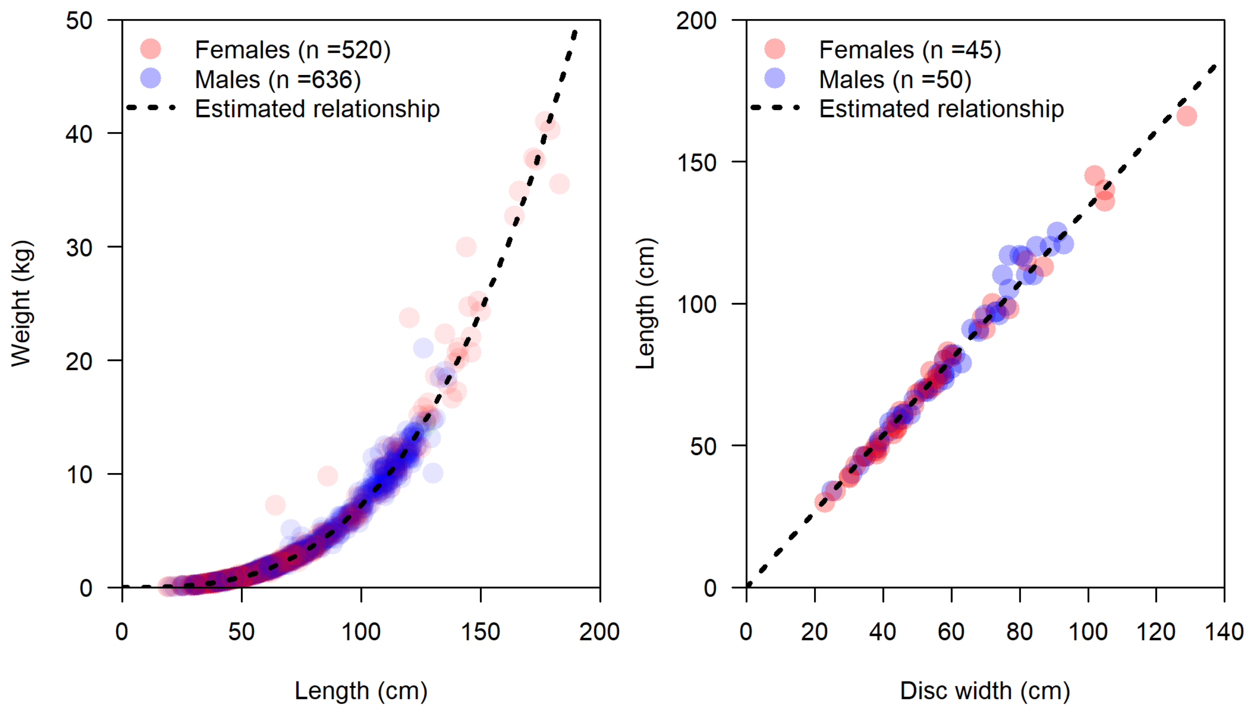

Figure 15: Estimated relationship between length and weight (left) and disc-width and length (right) for Big Skate. Colored points show observed values and the black line indicates the estimated relationship $W = 0.0000074924L^{2.9925}$.

740 ## 10.3 Model Results Figures

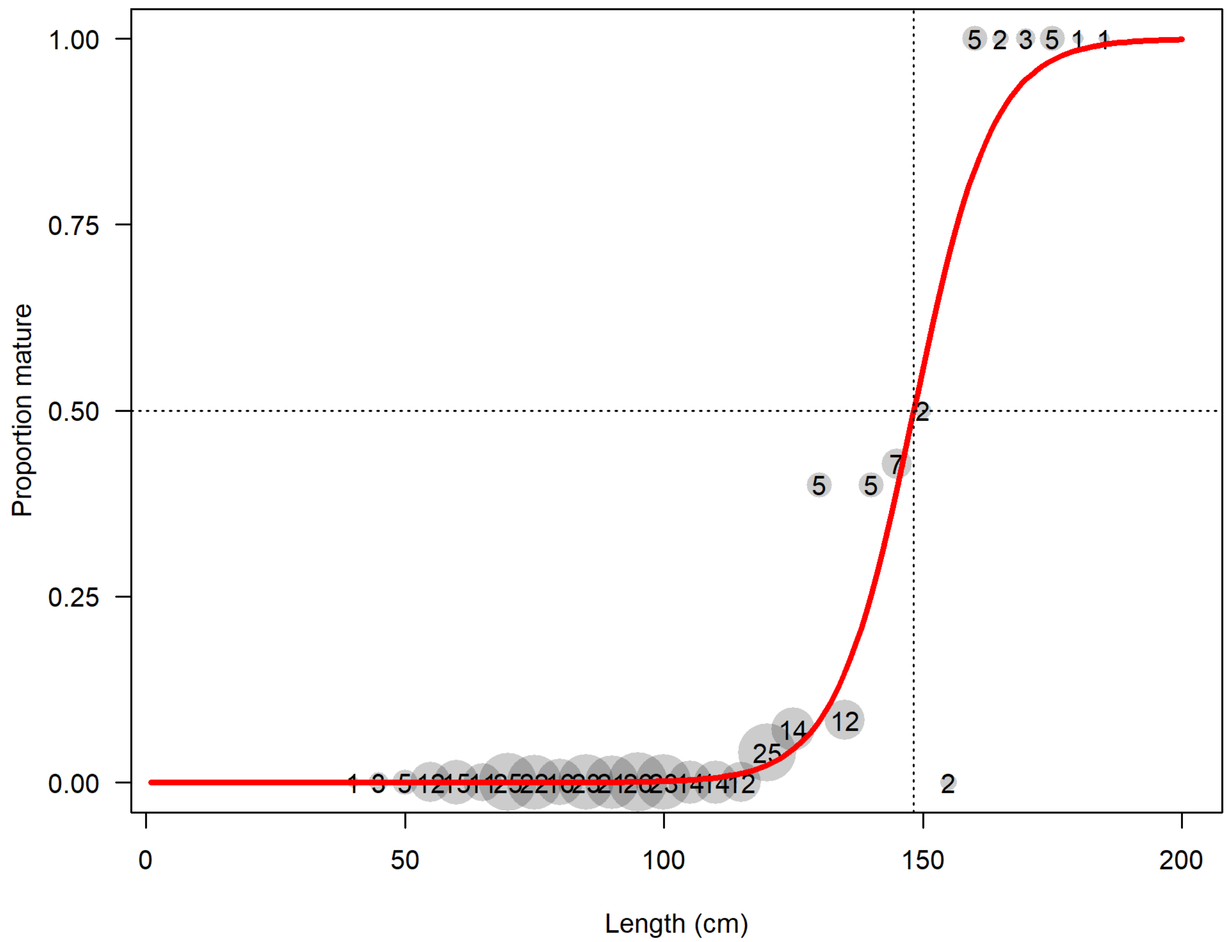

Figure 16: Estimated maturity relationship for female Big Skate. Gray points indicate average observed functional maturity within each length bin with point size proportional to the number of samples (indicated by text within each point).

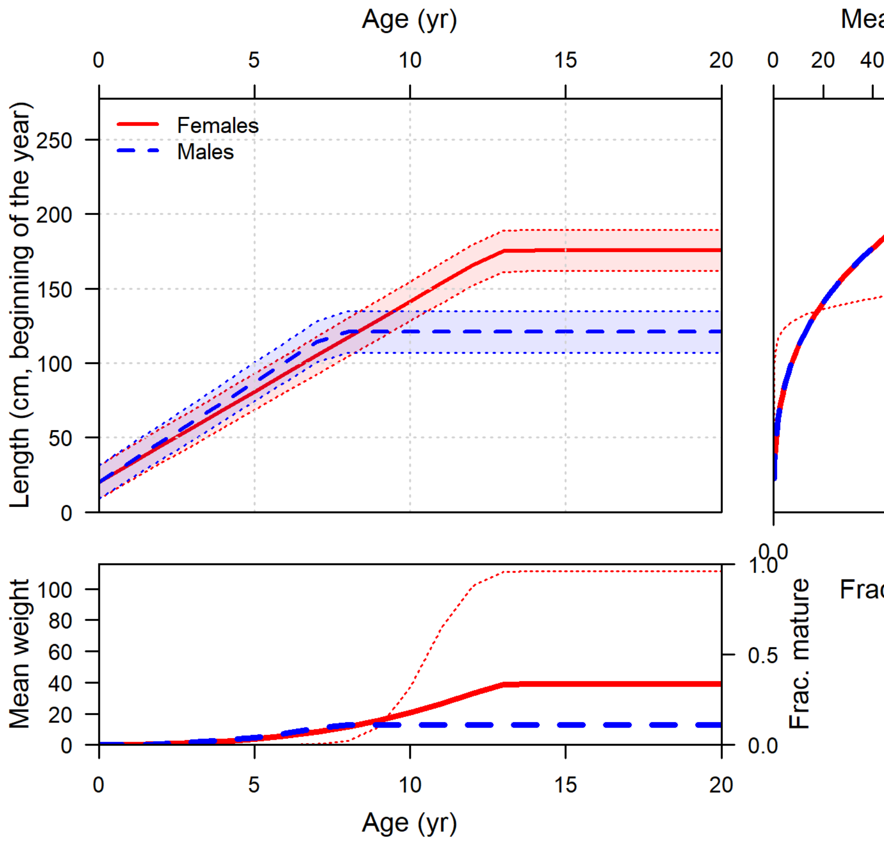
10.3.1 Growth and Selectivity



\begin{figure}[H] \begin{centering}
\caption{Estimated length-at-age for female and male Big Skate (top left panel). Shaded areas indicate 95% intervals for distribution of lengths at each age. Values represent beginning-of-year growth. Weight (thick line) and maturity (thin line) are shown in the top-right and lower-left panels as a function of length and age, respectively, where the values-at-age are calculated by mapping the length-based relationships through the estimated distribution of length at each age.} \end{centering} \end{figure}

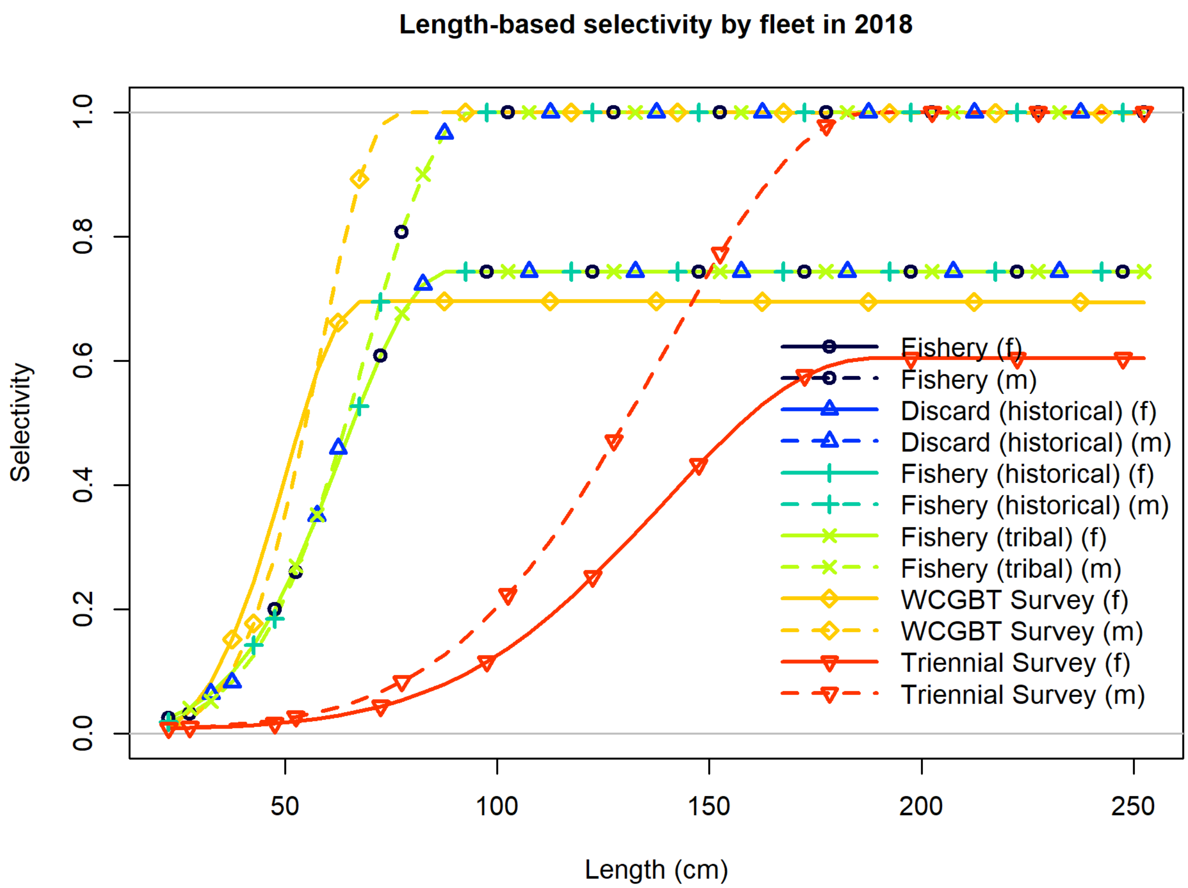


Figure 17: Selectivity at length for all of the fleets in the base model.

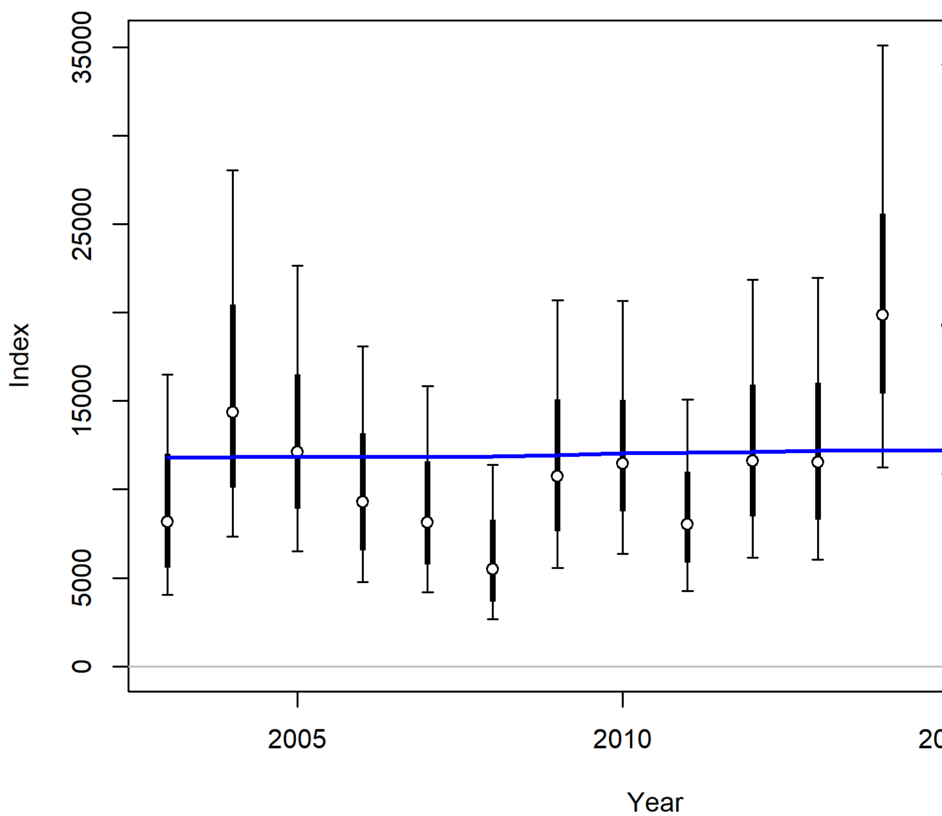
10.3.2 Fits to the Data



\begin{figure}[H] \begin{centering}
\caption{Fit to index data for WCGBT Survey. Lines indicate 95% uncertainty interval around index values. Thicker lines indicate input uncertainty before addition of estimated additional uncertainty parameter. The blue line indicates the model estimate.}
\end{centering} \end{figure}

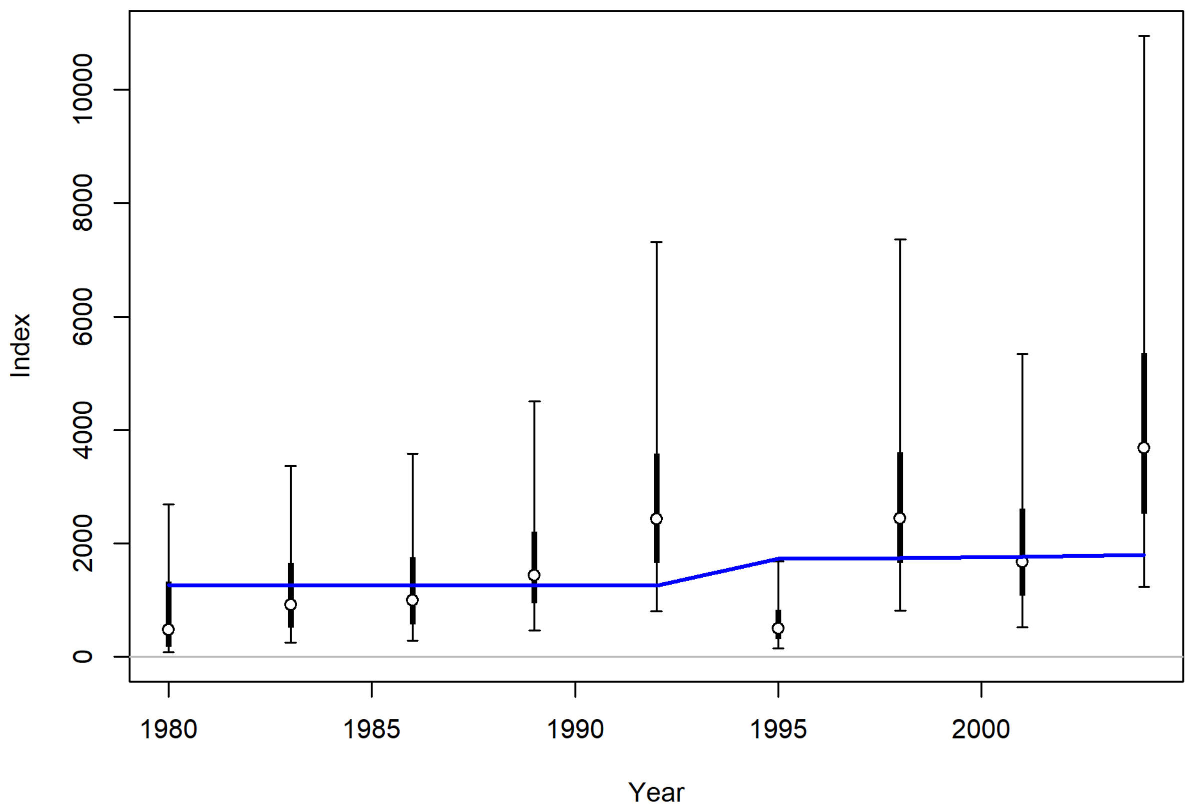


Figure 18: Fit to index data for Triennial Survey. Lines indicate 95% uncertainty interval around index values. Thicker lines indicate input uncertainty before addition of estimated additional uncertainty parameter. The blue line indicates the model estimate with a change between 1992 and 1995 associated with the estimated change in catchability.

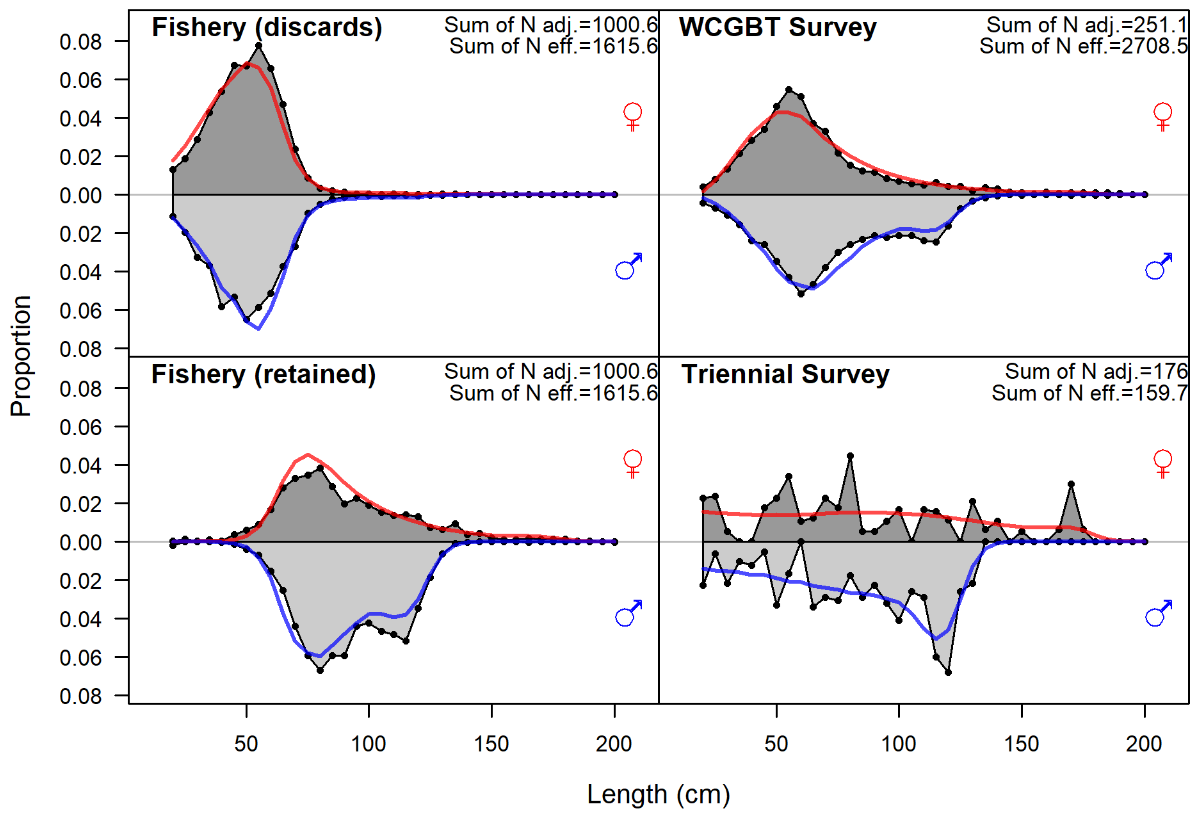

Figure 19: Fits to length comp data, aggregated across time by fleet.

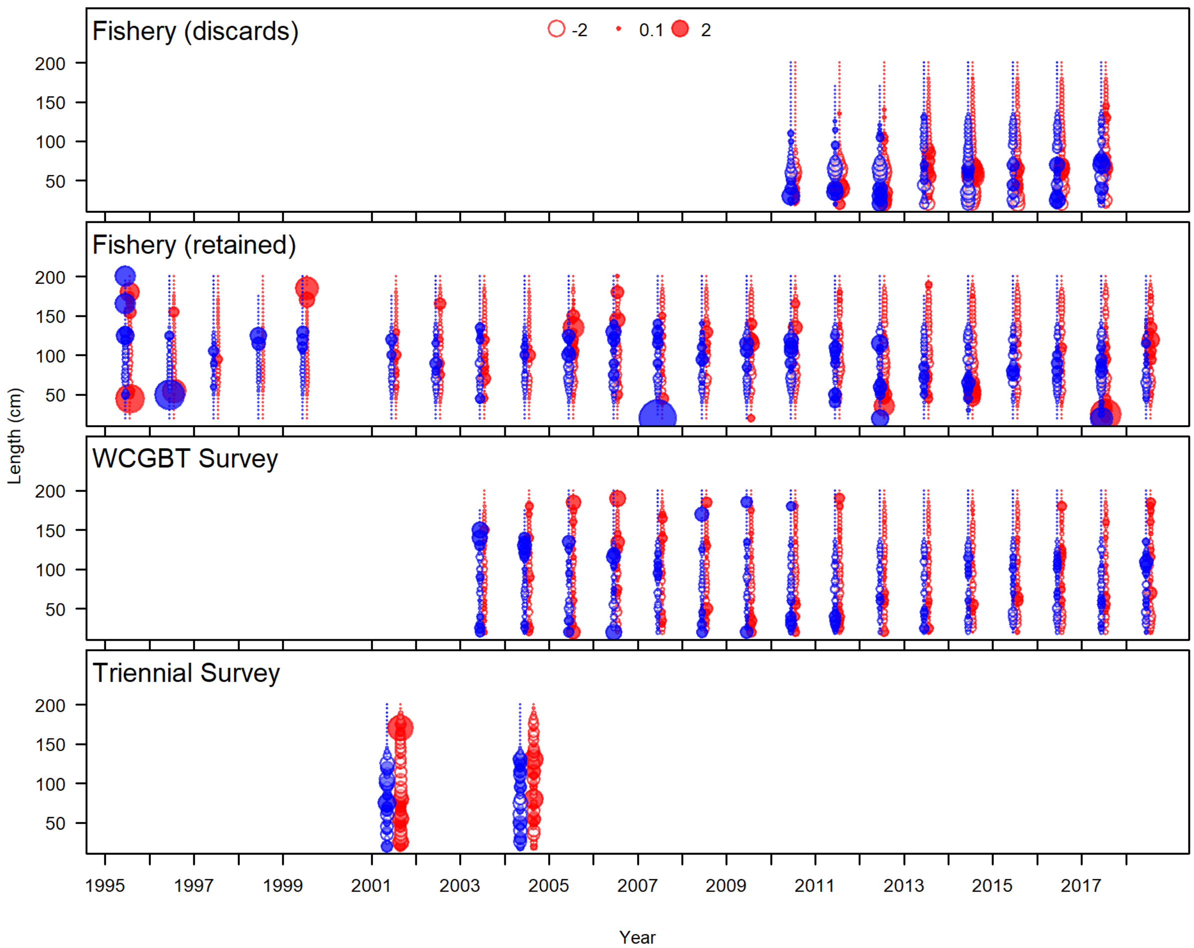

Figure 20: Pearson residuals for length comp data for all years and fleets, with females in red and males in blue.

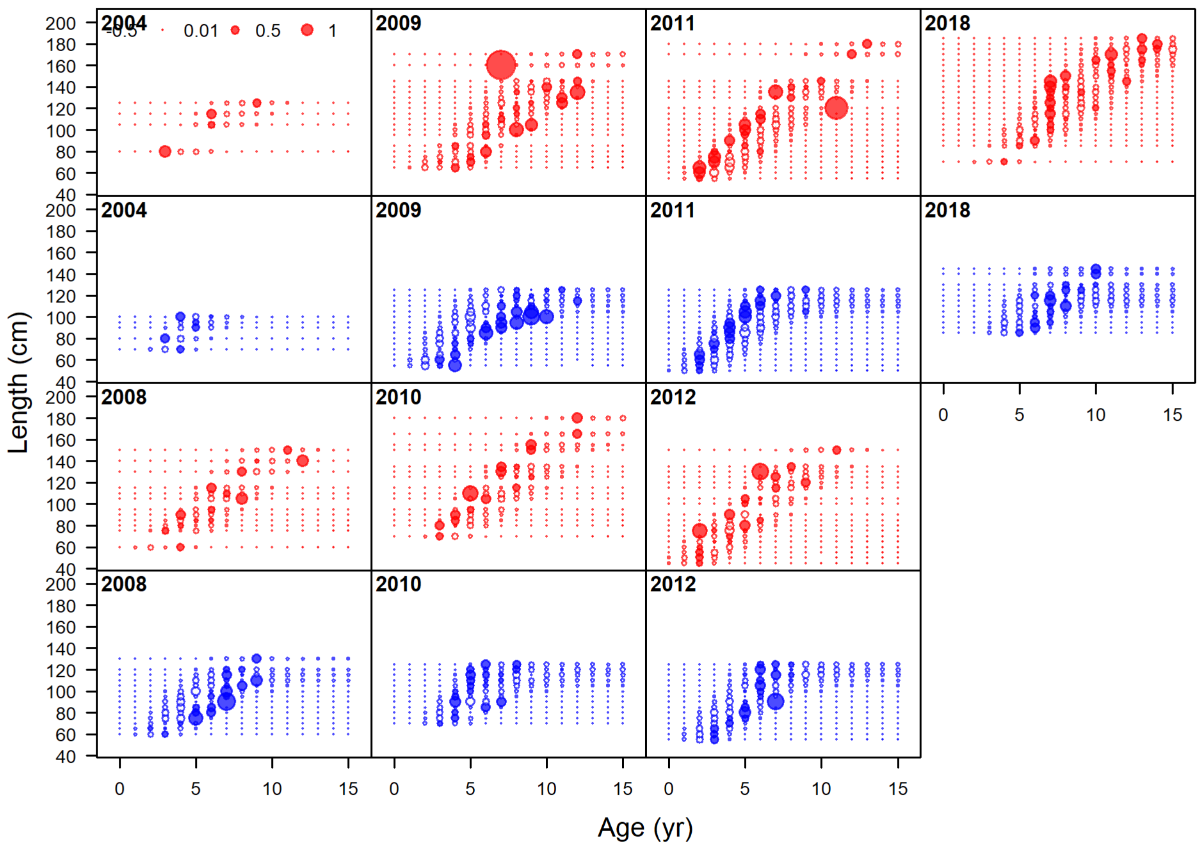

Figure 21: Pearson residuals for the fit to conditional age-at-length data from the fishery.

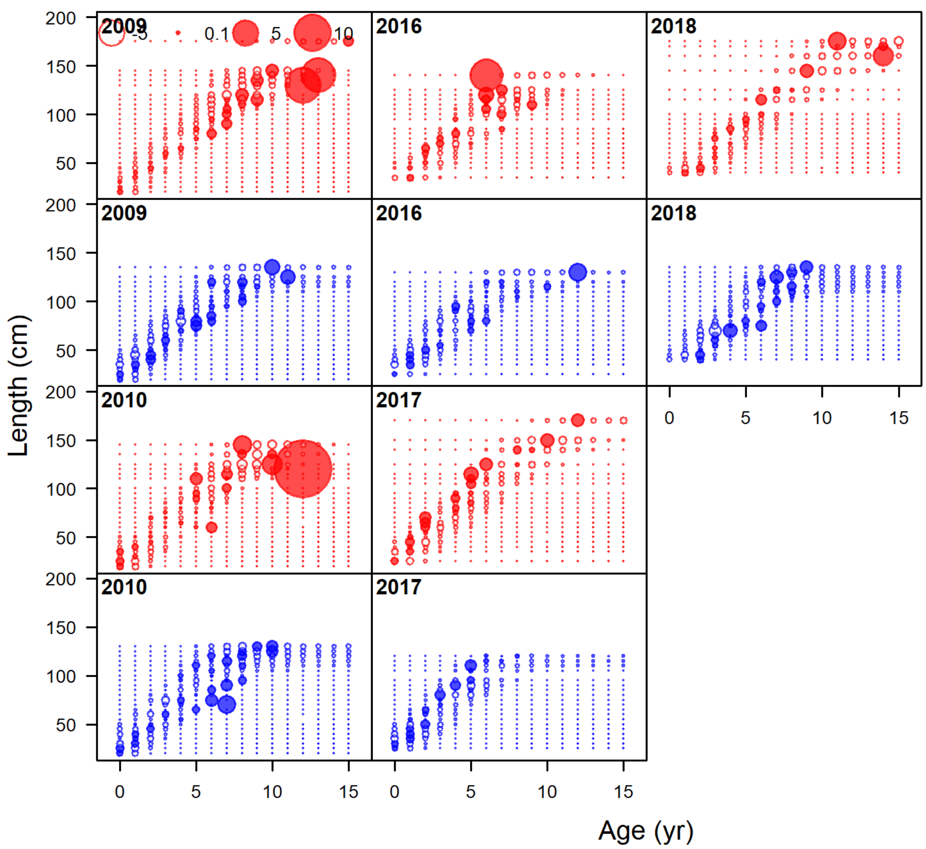

Figure 22: Pearson residuals for the fit to conditional age-at-length data from the WCGBT Survey.

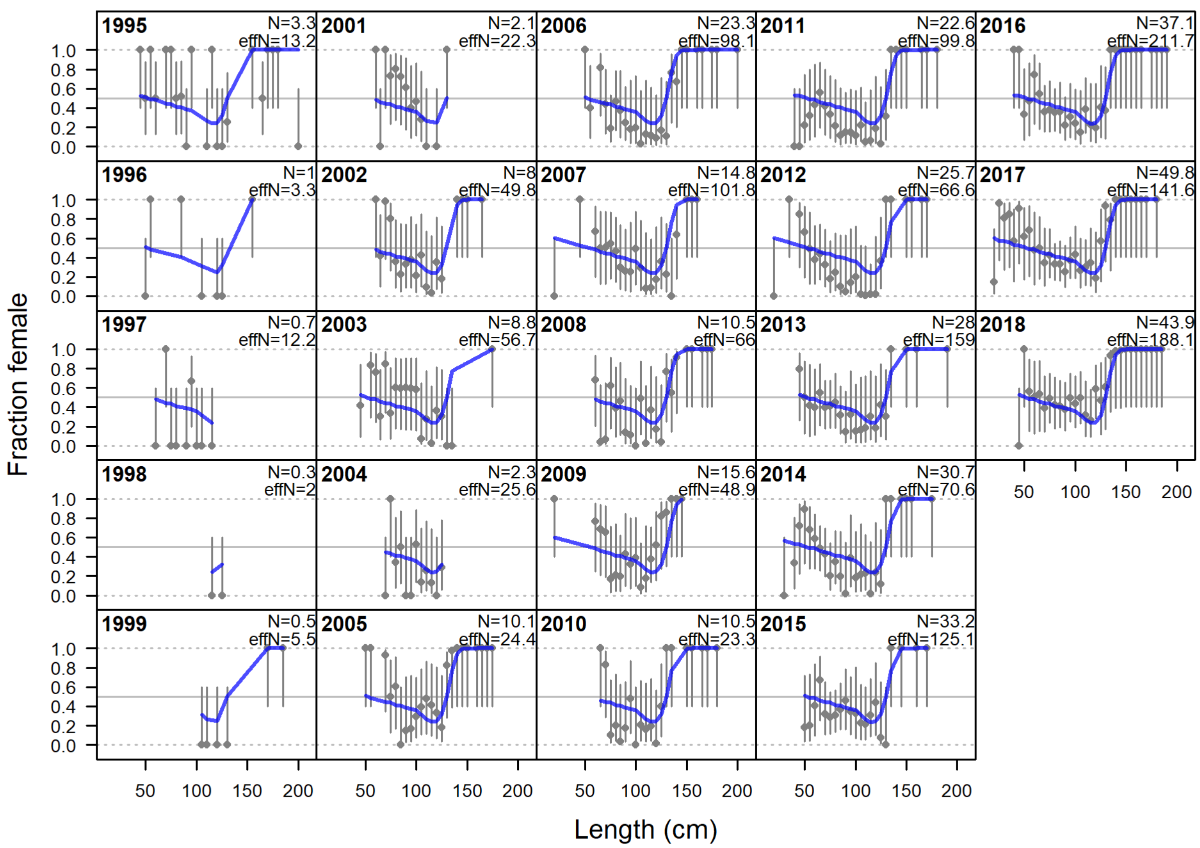

Figure 23: Observed sex ratios (points) from the fishery length comp data with 75% intervals (vertical lines) calculated as a Jeffreys interval based on the adjusted input sample size. The model expectation is shown in the blue line.

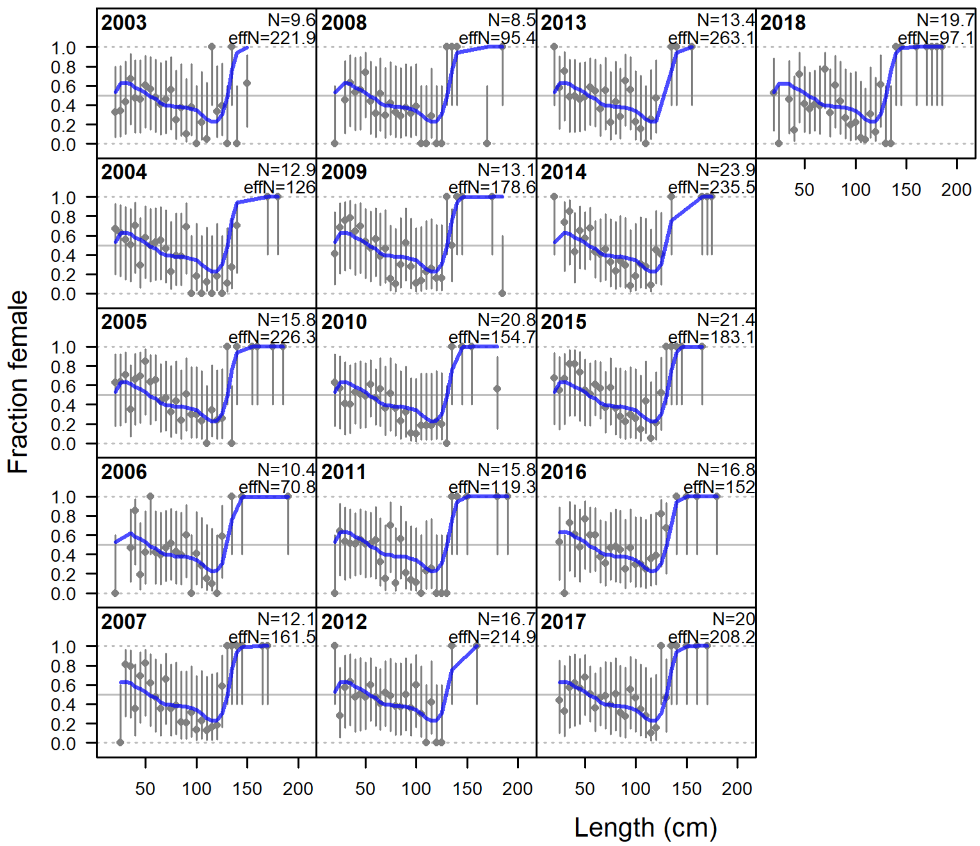

Figure 24: Observed sex ratios (points) from the WCGBT Survey length comp data with 75% intervals (vertical lines) calculated as a Jeffreys interval based on the adjusted input sample size. The model expectation is shown in the blue line.

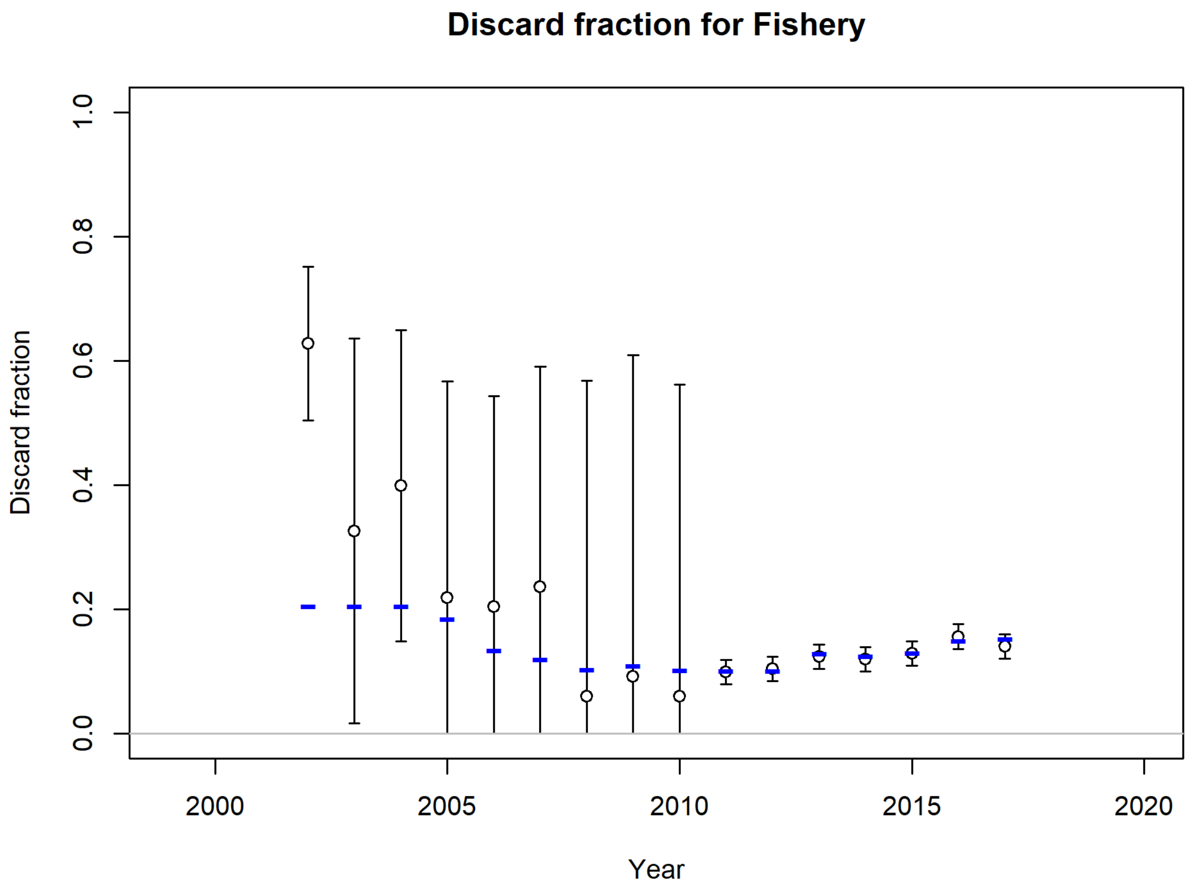

Figure 25: Fit to the discard fraction estimates. Points are model estimates with 95% uncertainty intervals. The model estimate is shown in the blue lines.

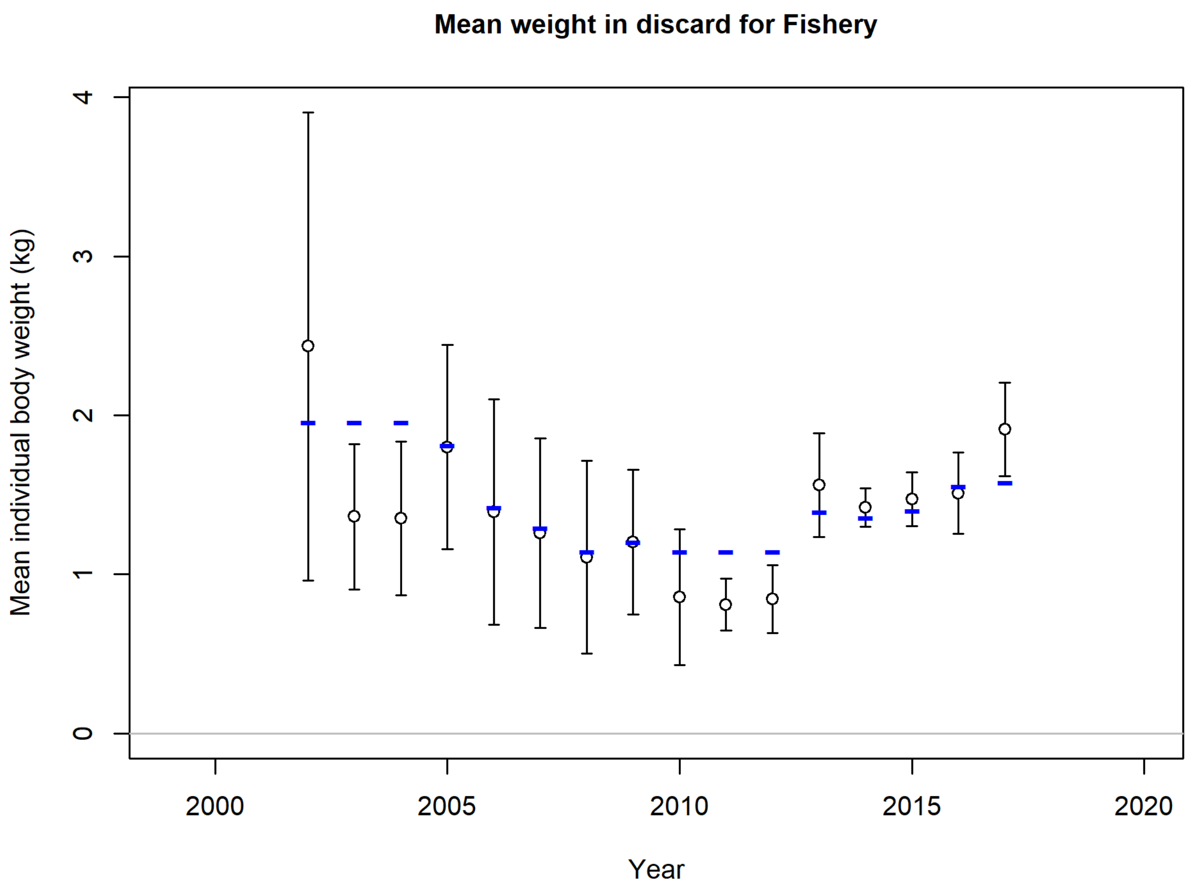

Figure 26: Fit to the mean weight of the discards. Points are model estimates with 95% uncertainty intervals. The model estimate is shown in the blue lines.

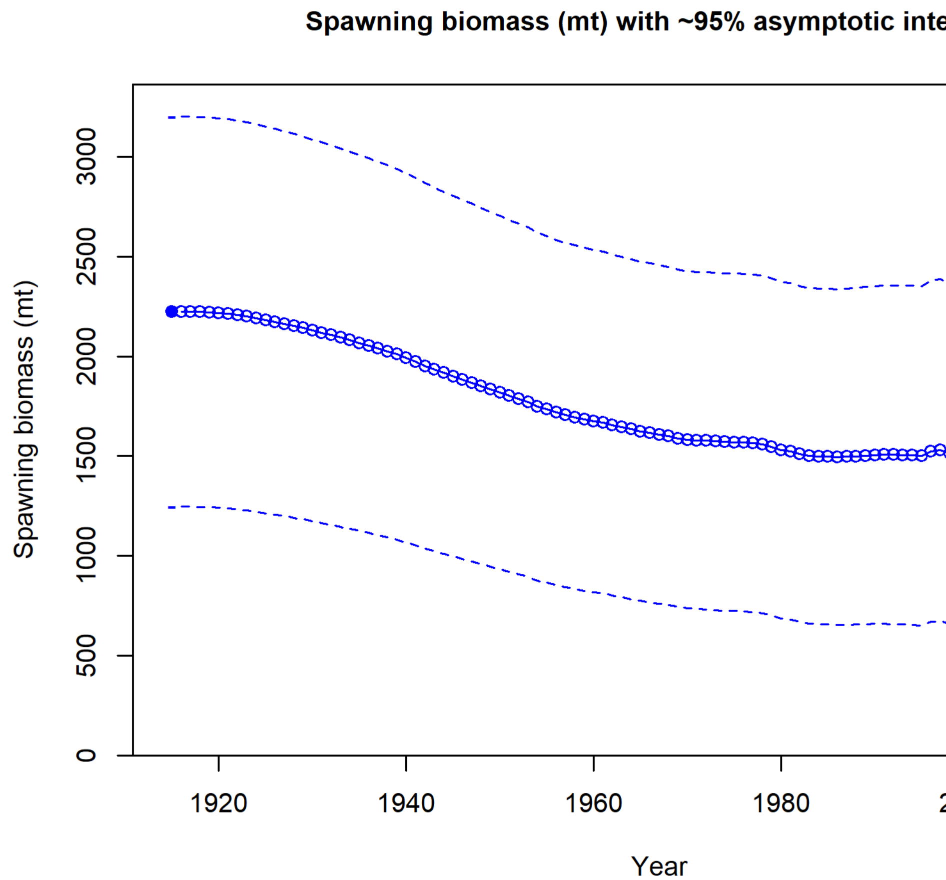
755 ### 10.3.3 Time Series Figures



756 \begin{figure}[H] \begin{centering}
757 \caption{Estimated spawning biomass (mt) with approximate 95% asymptotic intervals.}
758 \end{centering} \end{figure}

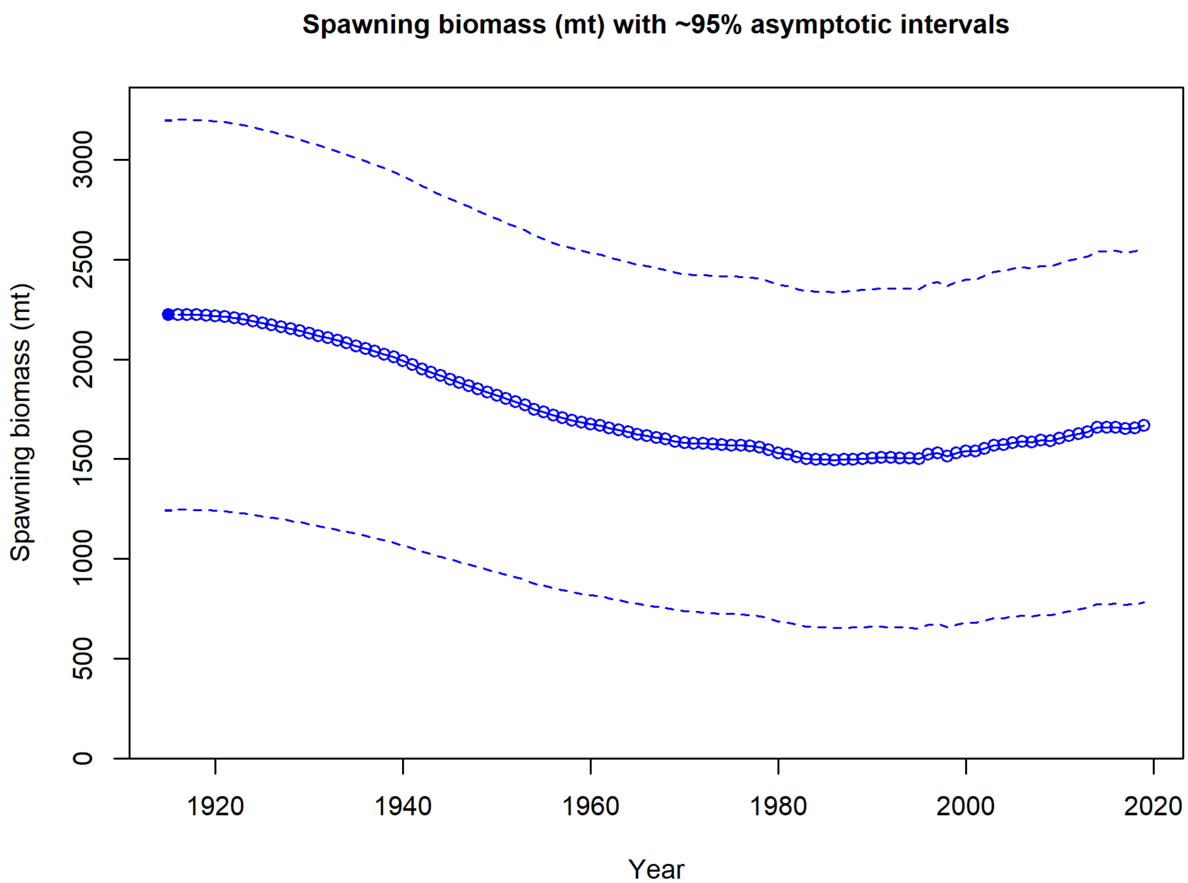


Figure 27: Estimated spawning biomass (mt) with approximate 95% asymptotic intervals.

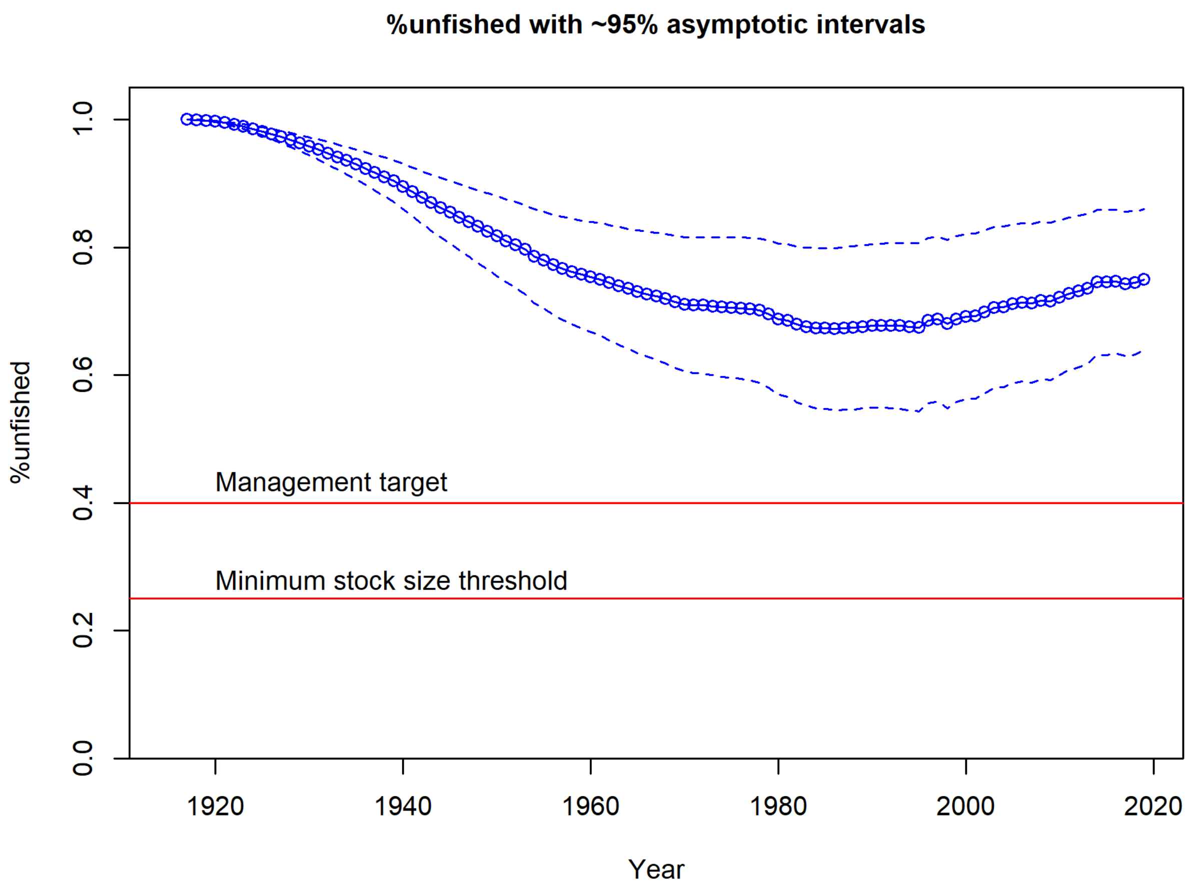

Figure 28: Estimated spawning depletion with approximate 95% asymptotic intervals.

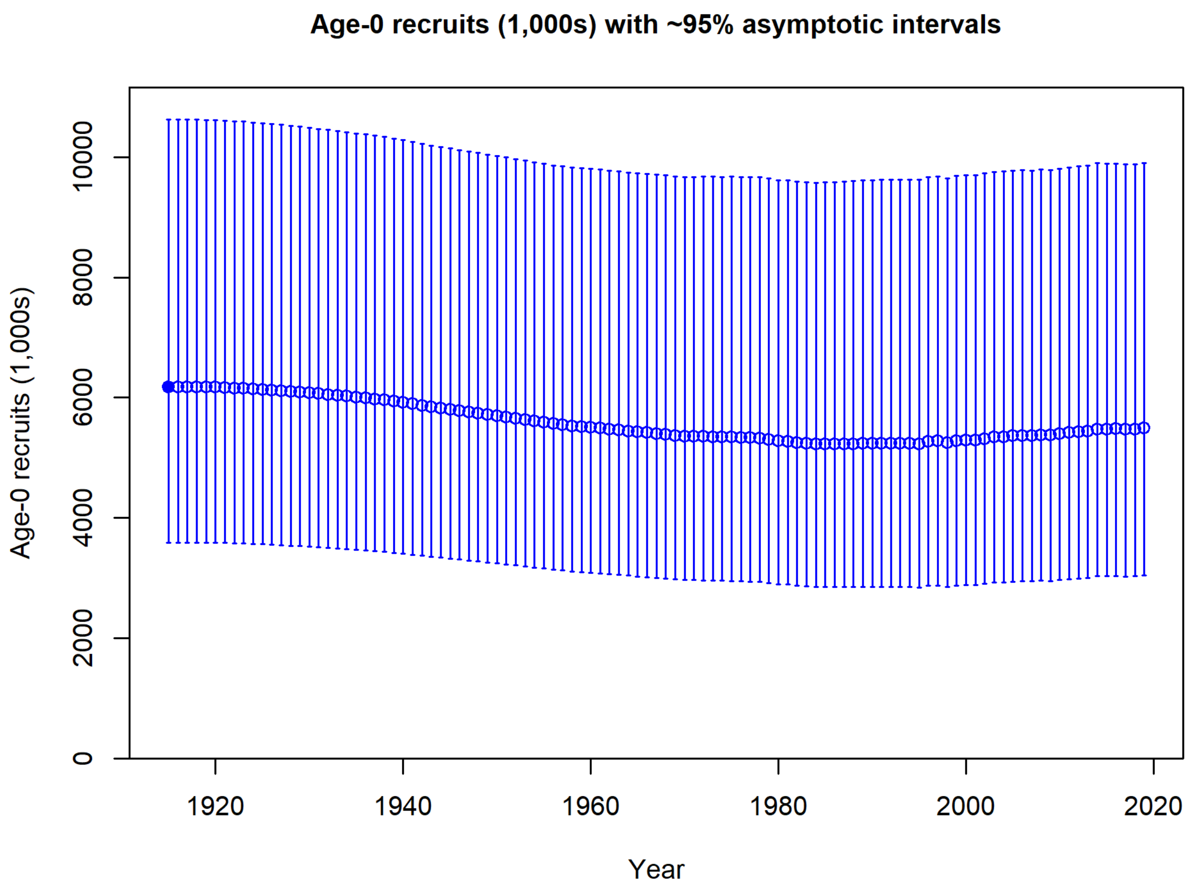

Figure 29: Estimated time-series of recruitment for Big Skate.

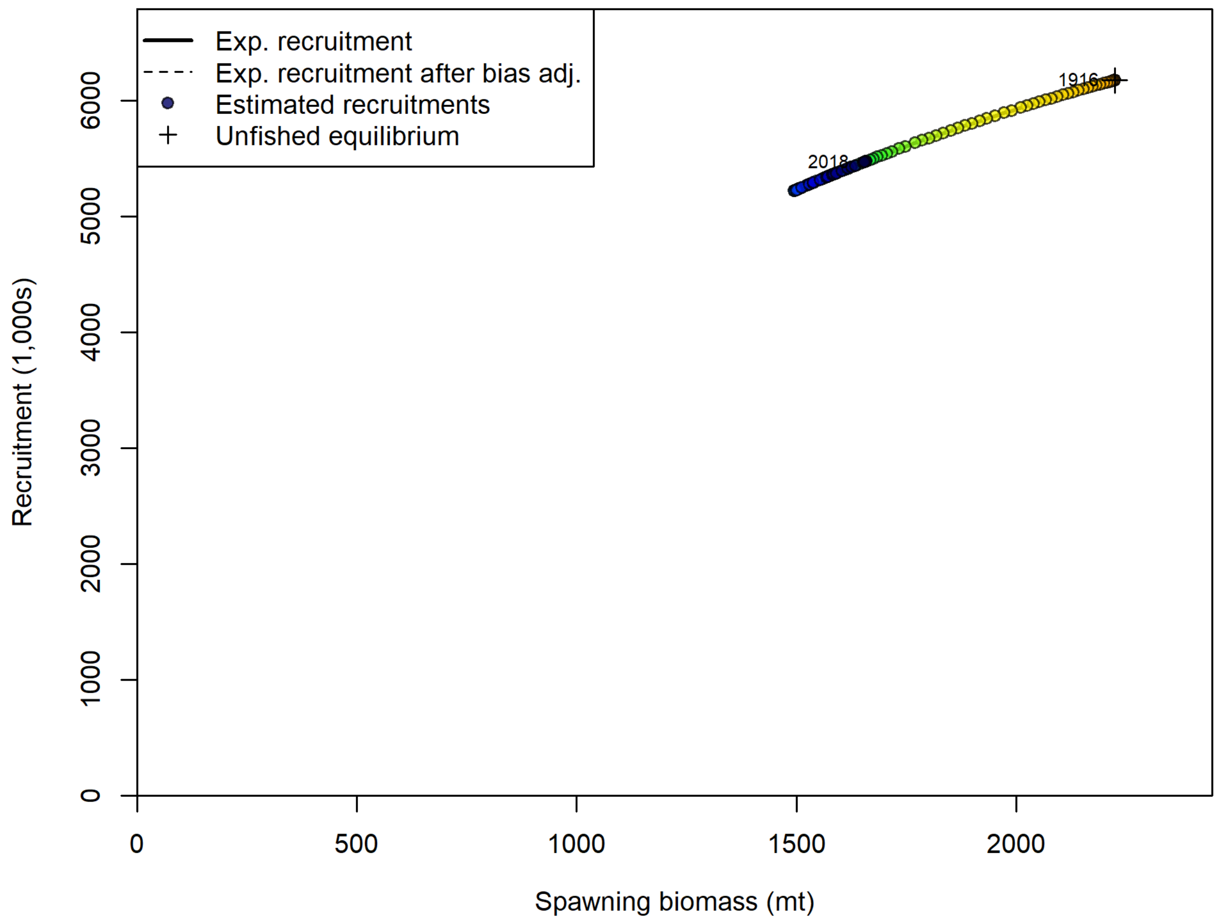

Figure 30: Estimated recruitment and the assumed stock-recruit relationship.

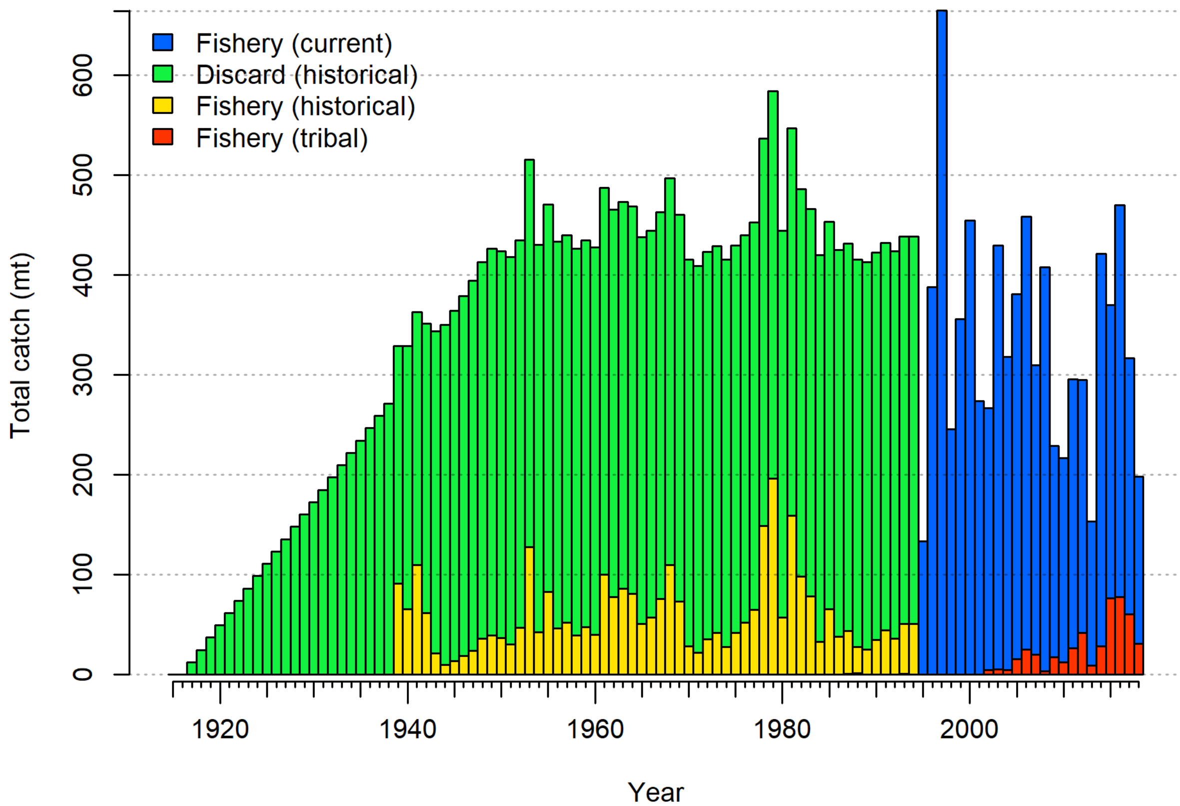

Figure 31: Estimated total catch including discards estimated within the model. The historical discards shown in green have been scaled to account for an assumed 50% discard mortality but the discards in the recent period show both live and dead discards.

759 ### 10.3.4 Sensitivity Analyses and Retrospectives

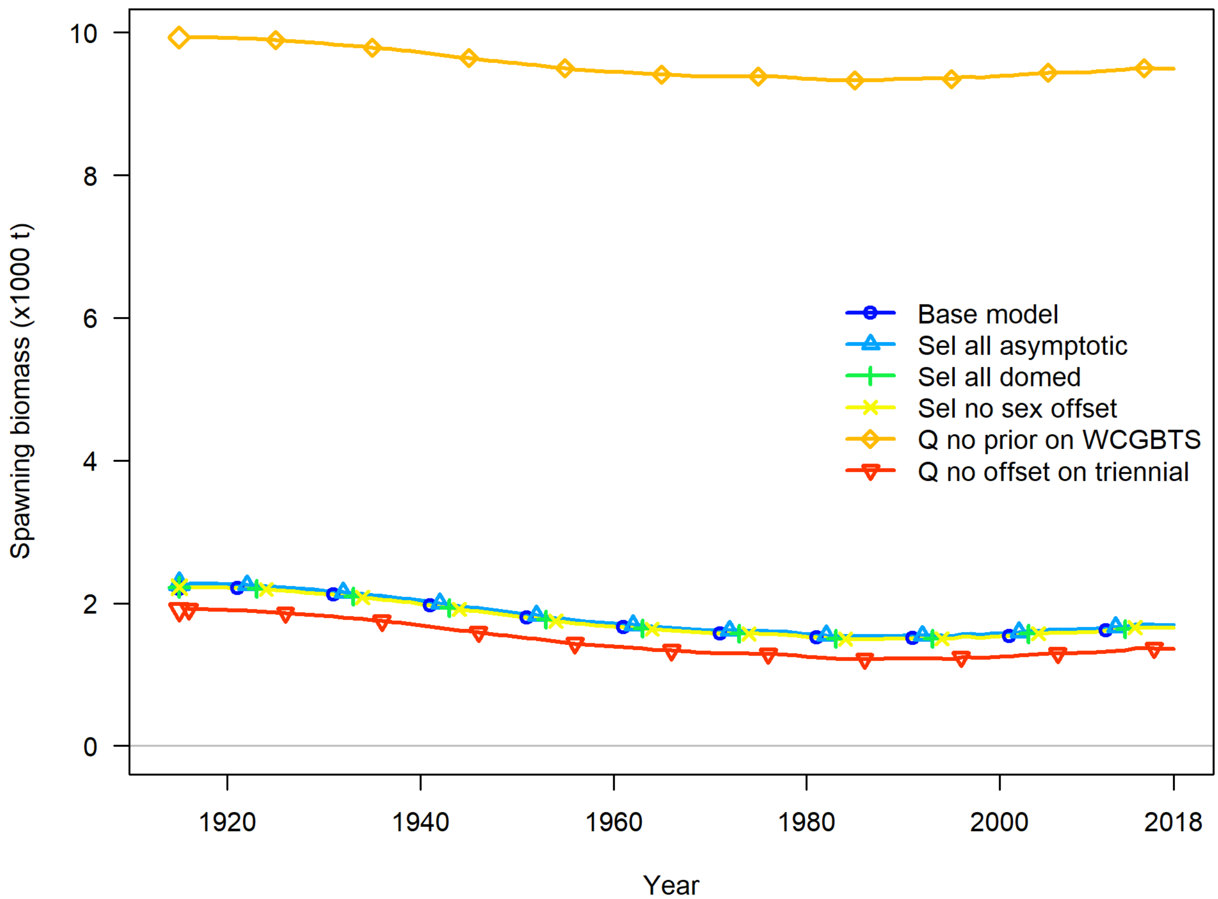

Figure 32: Time series of spawning biomass (mt) estimated in sensitivity analyses related to selectivity and catchability.

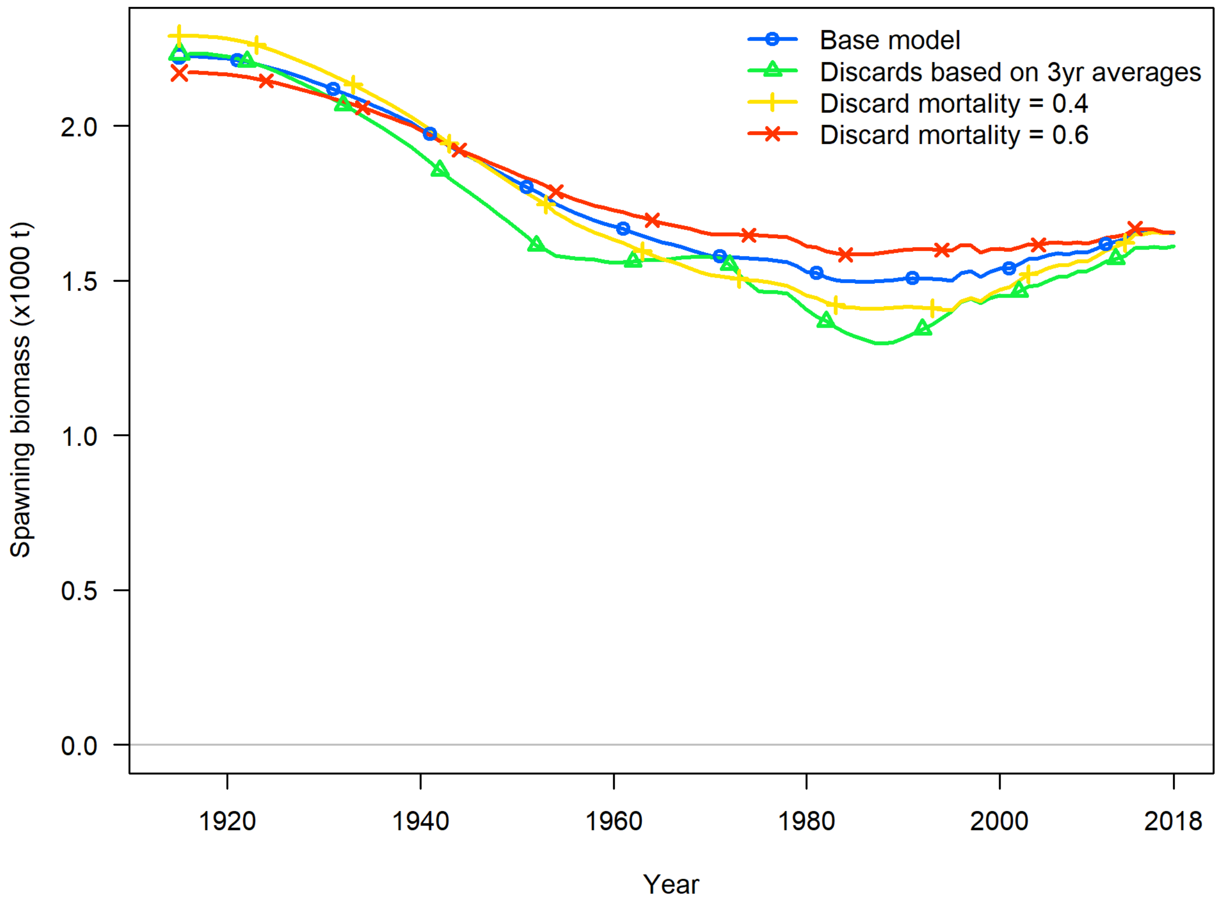

Figure 33: Time series of spawning biomass (mt) estimated in sensitivity analyses related to historic catch and discards.

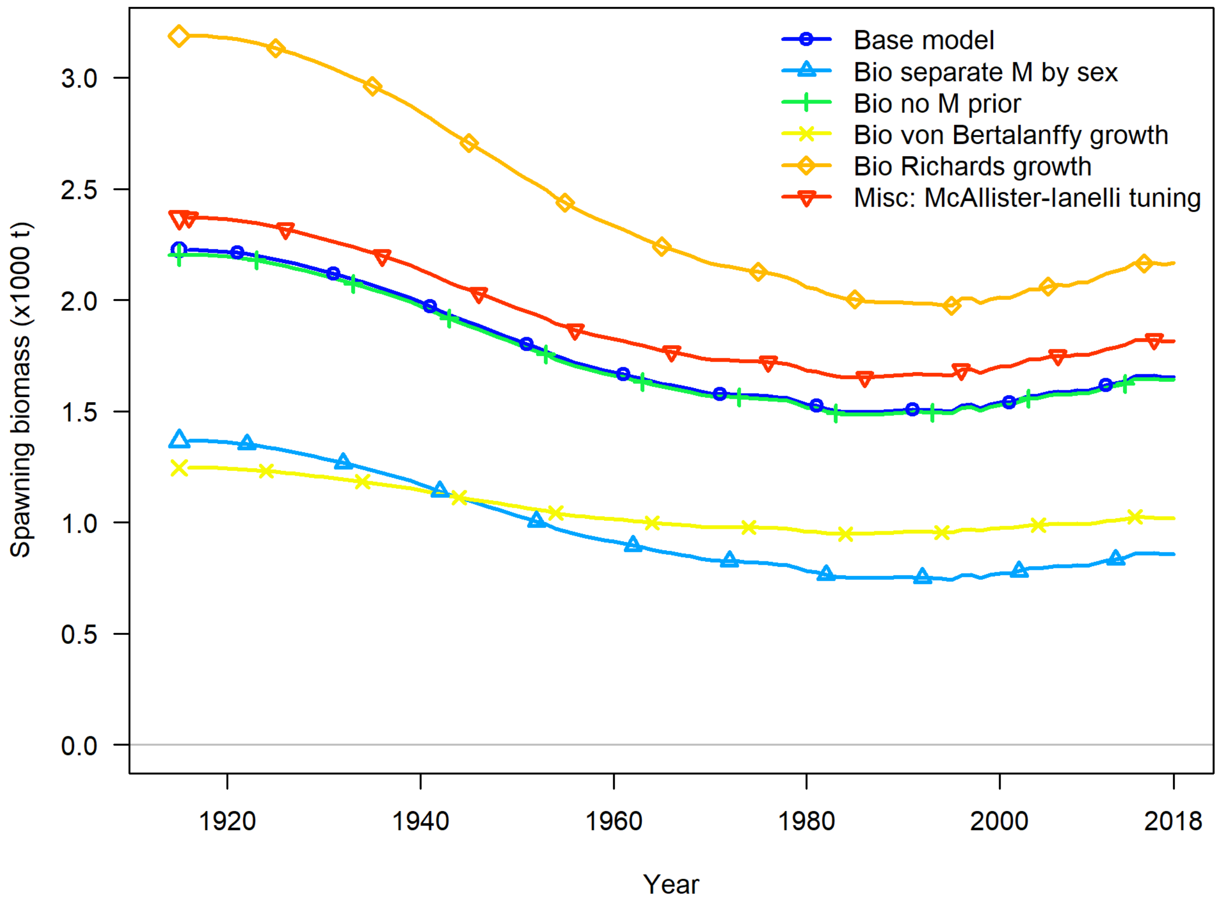

Figure 34: Time series of spawning biomass (mt) estimated in sensitivity analyses related to biology and other assumptions.

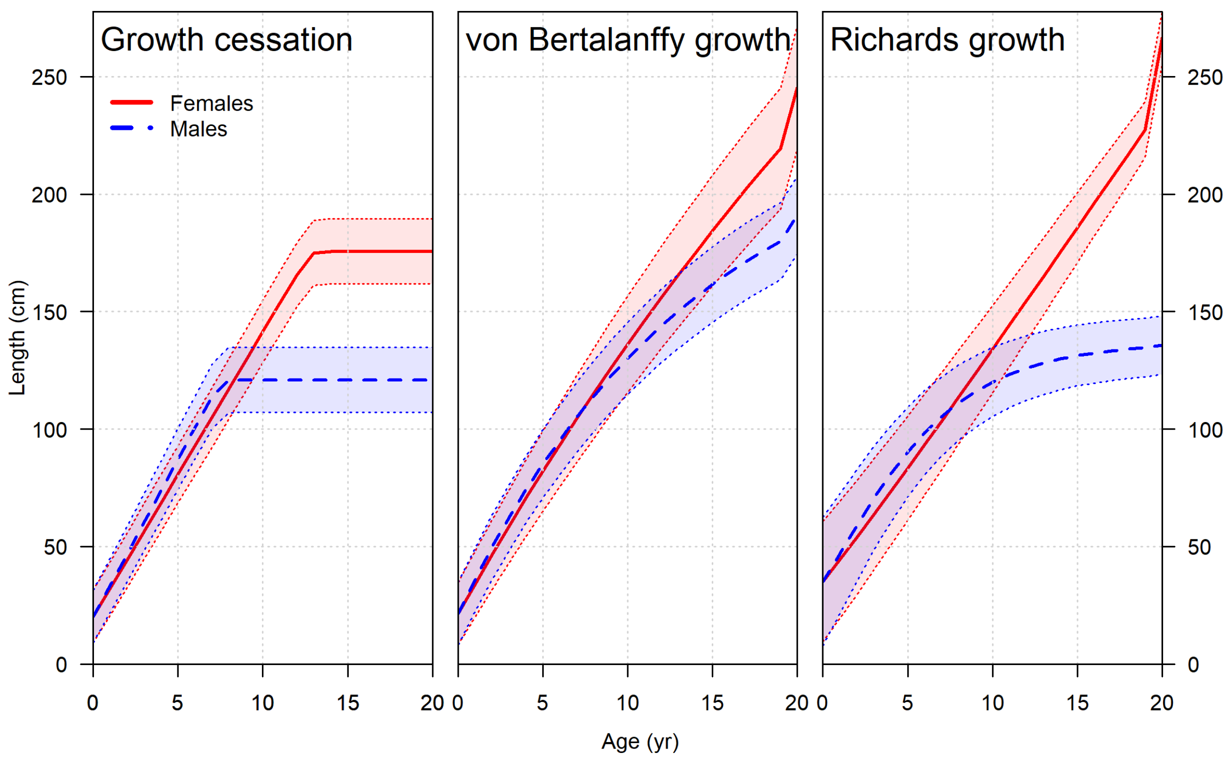

Figure 35: Comparison of the estimated growth curves from the sensitivities analyses.

760 ### 10.3.5 Likelihood Profiles

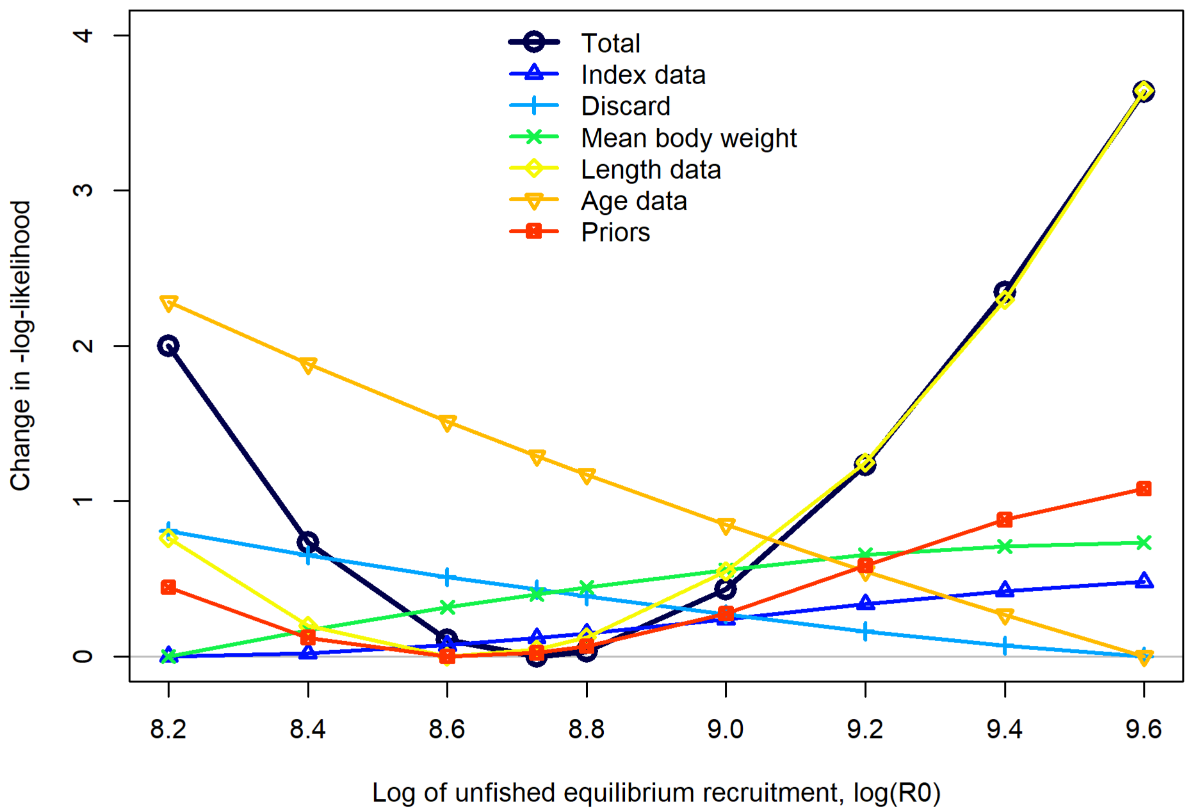

Figure 36: Likelihood profile over the log of equilibrium recruitment (R_0).

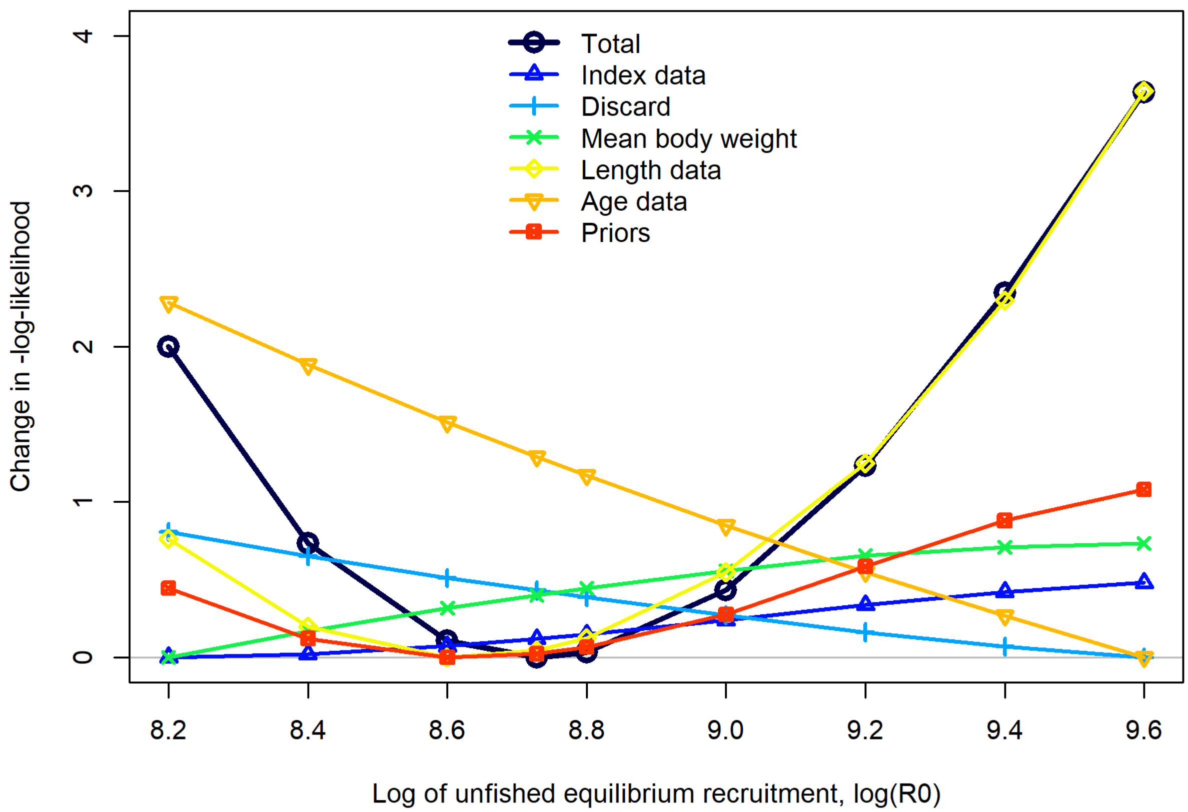

Figure 37: Likelihood profile over the log of equilibrium recruitment (R_0).

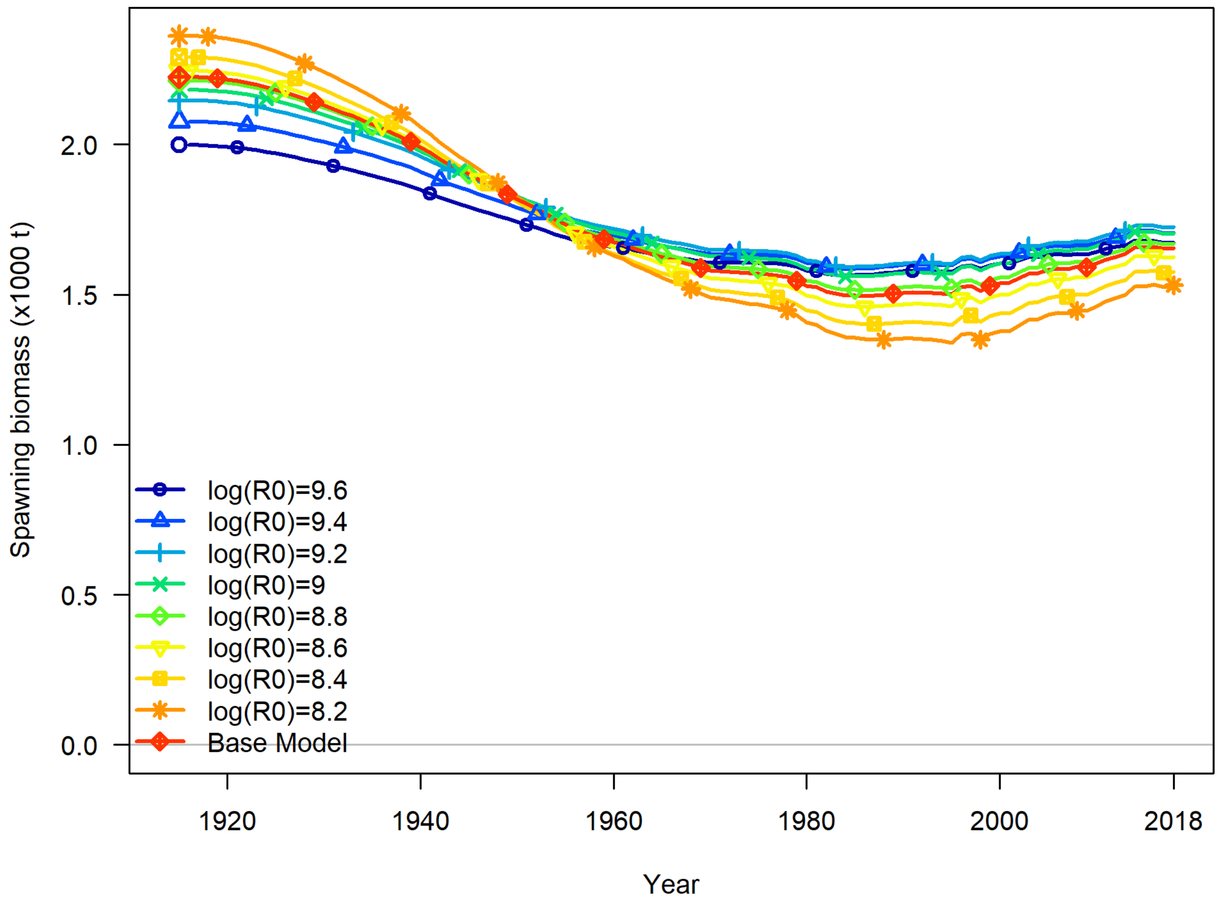

Figure 38: Time series of spawning biomass (mt) estimated for the models included in the profile over the log of equilibrium recruitment (R_0).

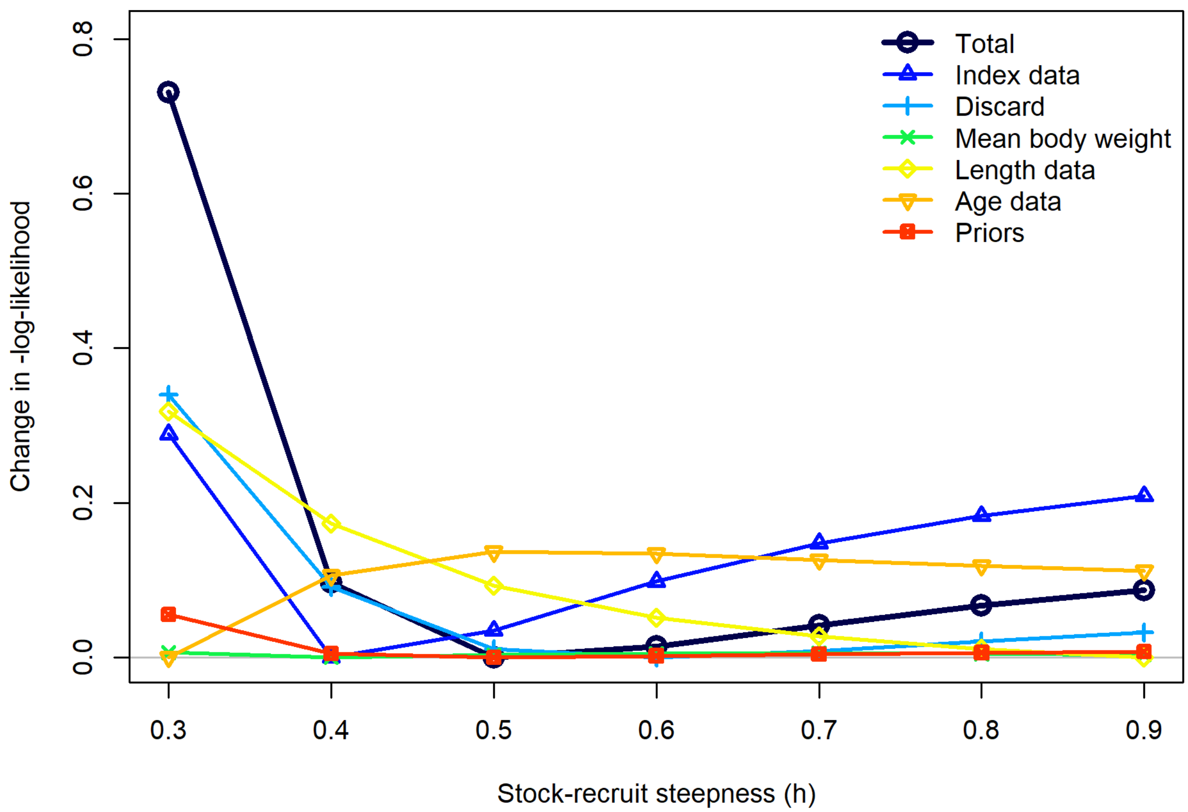

Figure 39: Likelihood profile over stock-recruit steepness (h).

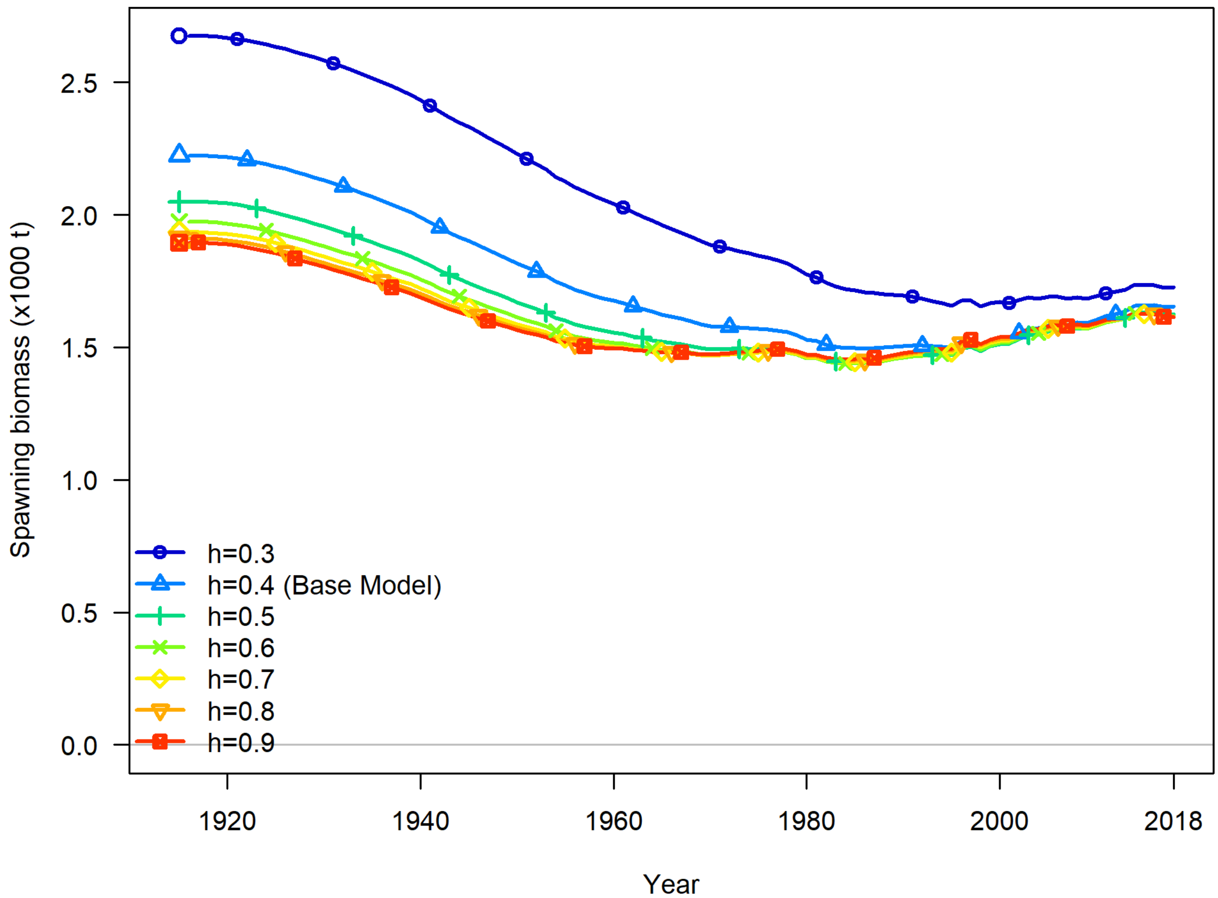

Figure 40: Time series of spawning biomass (mt) estimated for the models included in the profile over stock-recruit steepness (h).

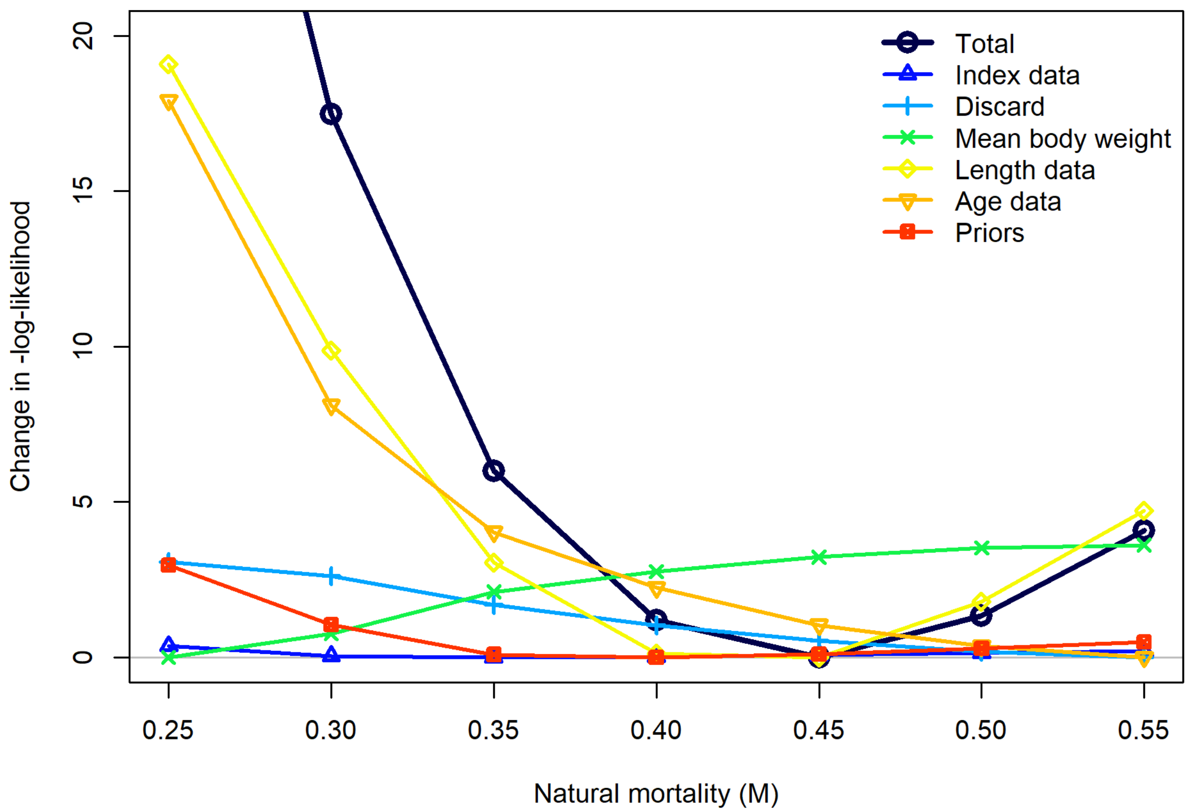

Figure 41: Likelihood profile over natural mortality (M).

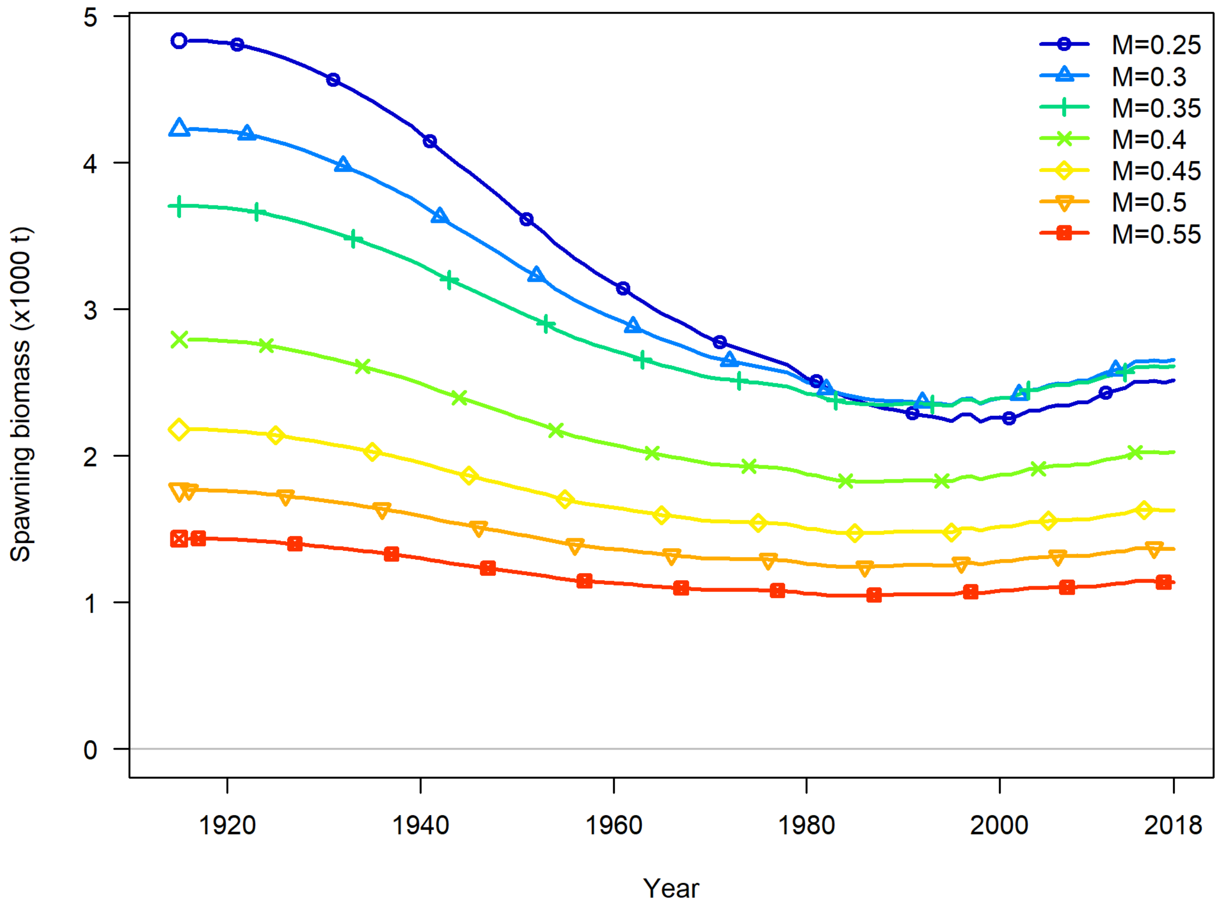

Figure 42: Time series of spawning biomass (mt) estimated for the models included in the profile over natural mortality (M).

10.3.6 Reference Points and Forecasts

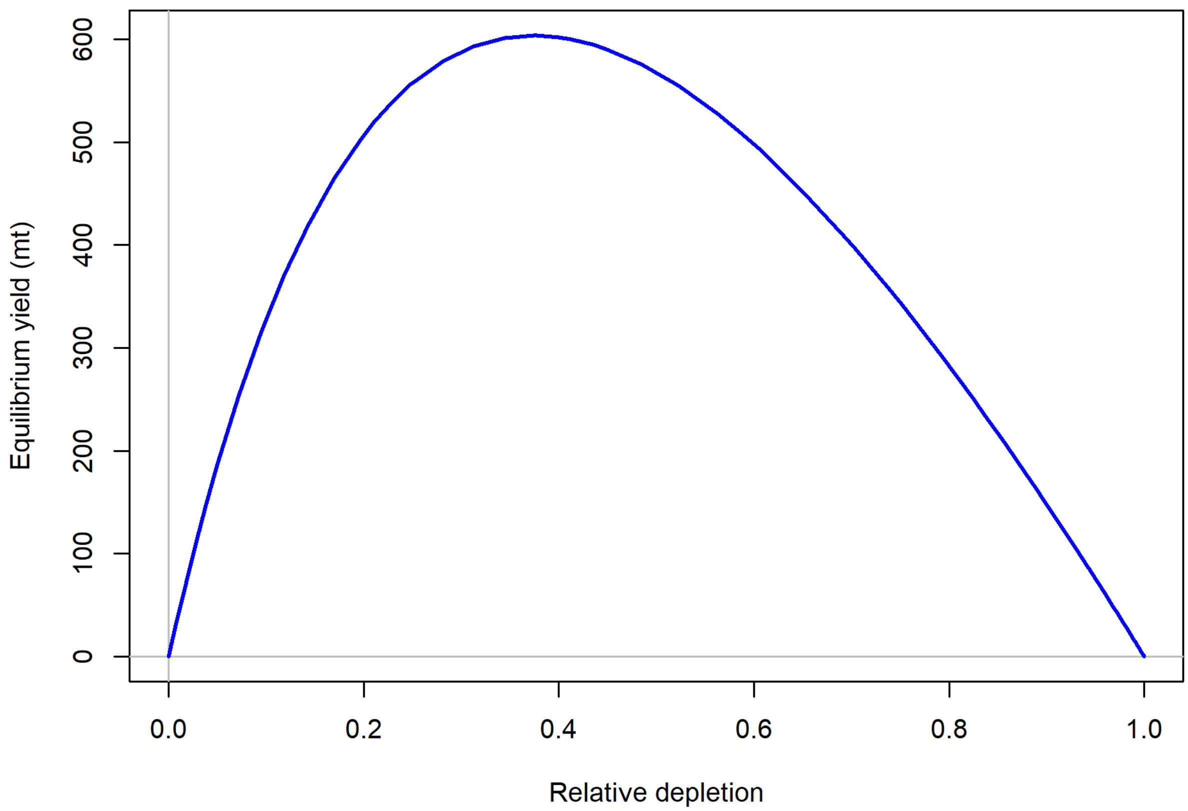

Figure 43: Equilibrium yield curve for the base case model. Values are based on the fishery selectivity and with steepness fixed at 0.4.

Appendix A. Detailed fits to length composition data

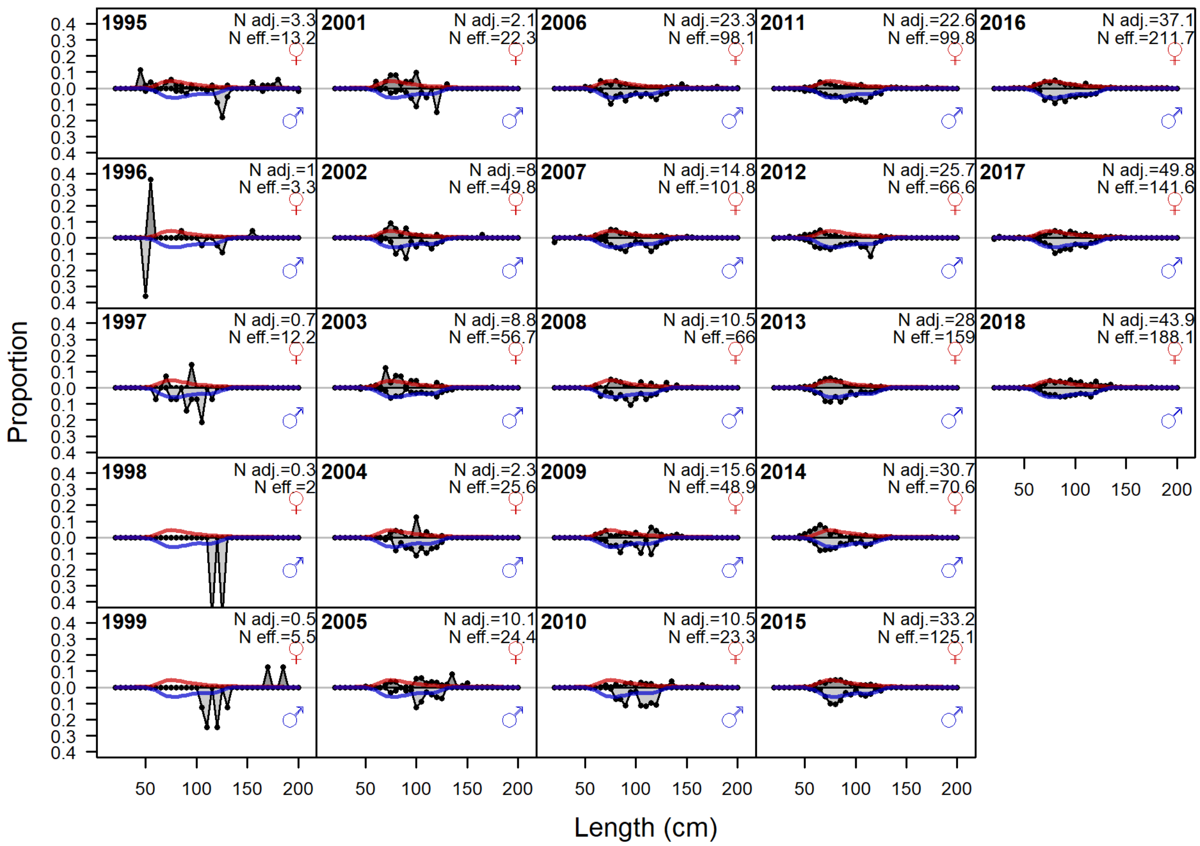

Figure A44: Length comps, retained, Fishery. 'N adj.' is the input sample size after data_weighting adjustment. N eff. is the calculated effective sample size used in the McAllister_Iannelli tuning method.

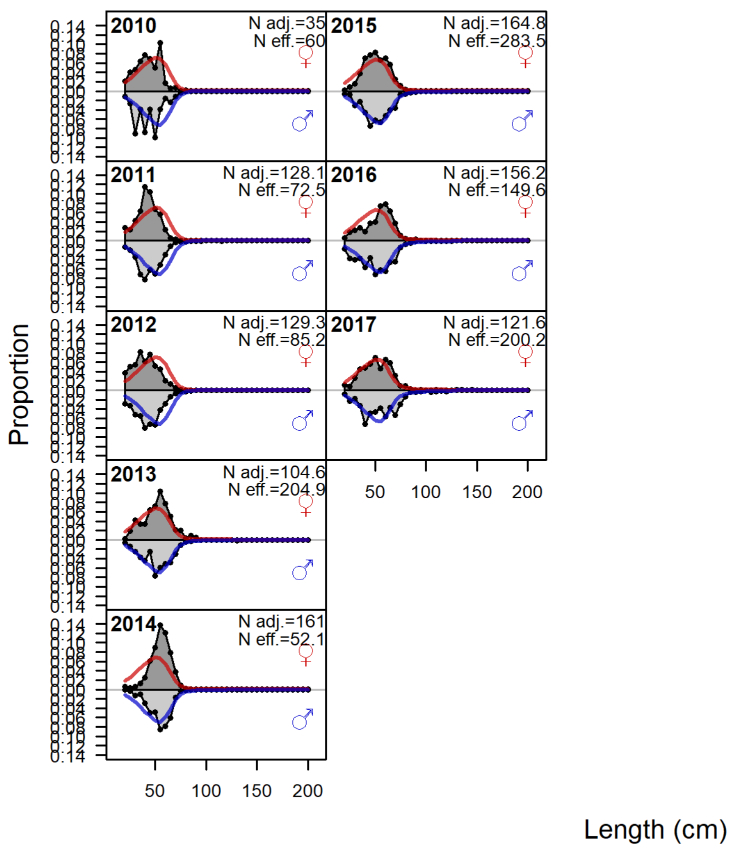

Figure A45: Length comps, discard, Fishery. 'N adj.' is the input sample size after data_weighting adjustment. N eff. is the calculated effective sample size used in the McAllister_Iannelli tuning method.

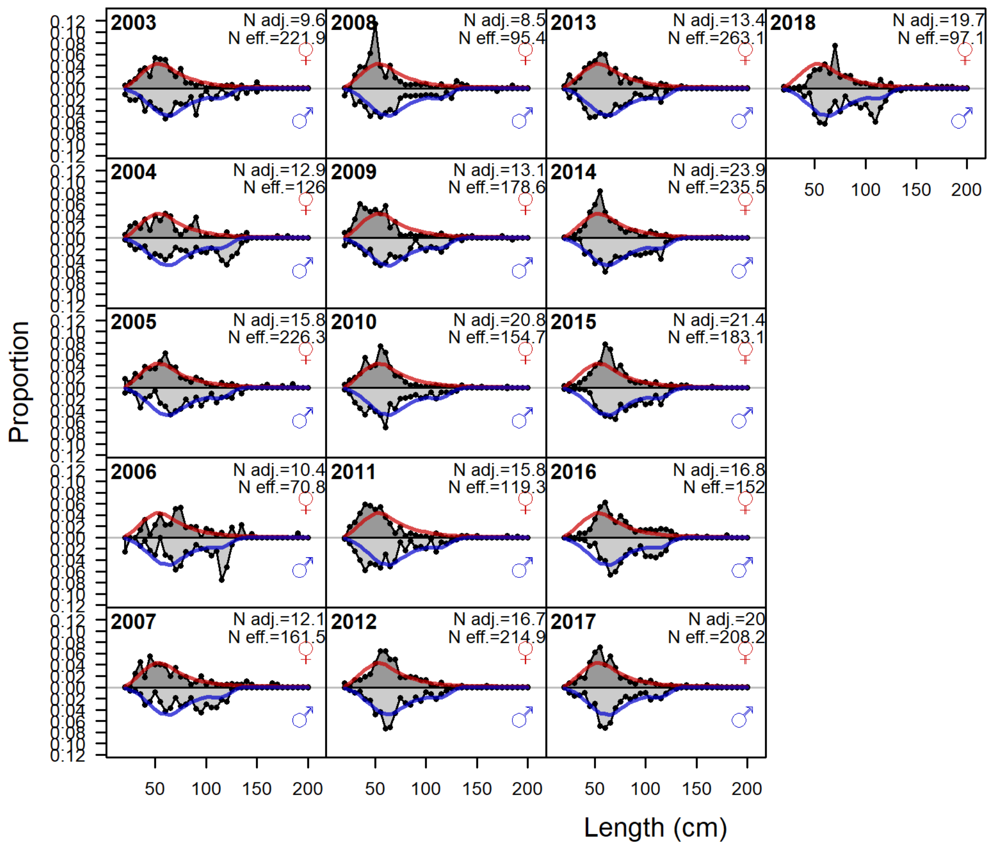

Figure A46: Length comps, whole catch, WCGBT Survey. 'N adj.' is the input sample size after data_weighting adjustment. N eff. is the calculated effective sample size used in the McAllister_Iannelli tuning method.

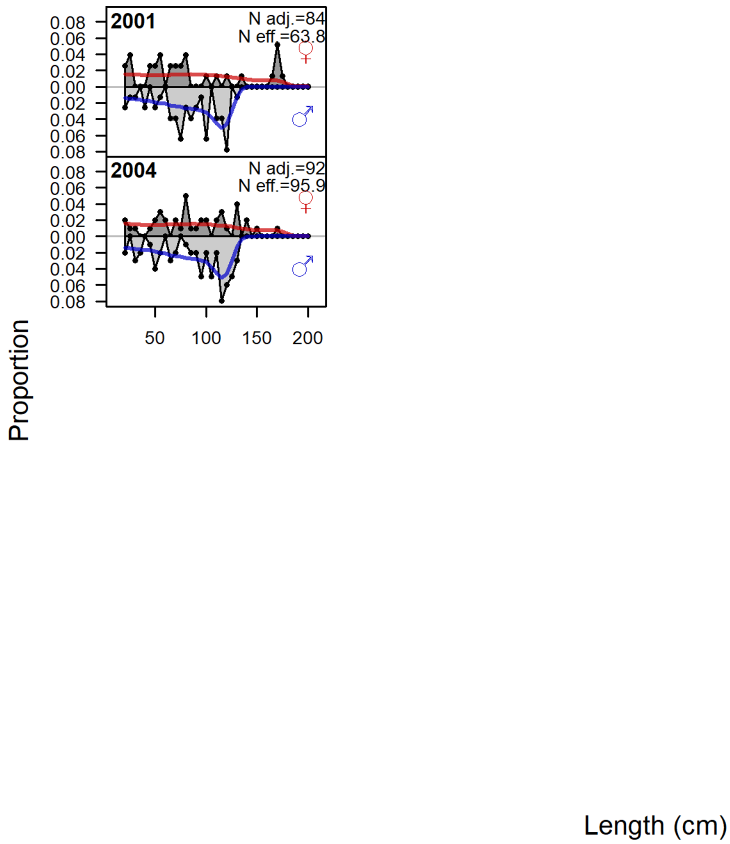

Figure A47: Length comps, whole catch, Triennial Survey. 'N adj.' is the input sample size after data_weighting adjustment. N eff. is the calculated effective sample size used in the McAllister_Iannelli tuning method.
